**Running headline:** Multiparametric MRI to monitor anti-tumoral drugs

**Key words:** Apparent diffusion coefficient of water (ADC), blood volume fraction (BVf), brain tumor, Contrast enhancement MRI, therapies, vessel size index (VSI).

## **Acknowledgements**

B.L. benefited from a doctoral grant from 'Agence national de la Recherche et de la technologie'. We thank Guerbet for providing Sinerem<sup>®</sup> and P846, the 'Institut National du Cancer', the 'Région Rhône-Alpes' and the 'Cancéropôle Lyon Auvergne Rhône-Alpes' for financial support.

## Abstract

Early imaging or blood biomarkers of tumor response are needed to customize anti-tumor therapy, on individual basis. This study evaluates the sensitivity and the relevance of five potential MRI biomarkers.

Sixty *Nude* rats were implanted with human glioma cells line (U-87 MG) and randomized in 3 groups: one group received an anti-angiogenic treatment (Sorafenib), a second a cytotoxic drug (BCNU) and the third group no treatment. Tumor volume, apparent diffusion coefficient (ADC) of water, blood volume fraction (BVf), microvessel diameter (VSI) and vessel wall integrity (CE) were monitored before and during treatment.

Sorafenib reduced tumor contrast enhancement as early as one day after treatment onset. Four days later tumor BVf was reduced and tumor VSI was increased. Fourteen days later ADC was increased and tumor growth rate was reduced. Under BCNU, ADC was increased and tumor growth rate was reduced 14 days after treatment onset. Thus, estimated MRI parameters were sensitive to treatment, at different times after treatment onset and in a treatment dependent way.

This study suggests that multiparametric MR monitoring could allow the assessment of new anti-tumor drugs and the optimization of therapies combinations.

## Introduction

Glioblastomas are the most common subtypes of rapidly growing primary brain tumors in adults. Being among the most angiogenic human tumors, they are characterized by remarkable proliferative vascular components [1]. Their aggressiveness is mainly due to their ability to stimulate the formation of new blood vessels [2].

Despite active efforts in therapeutics such as surgery, radiotherapy and chemotherapy, gliomas still have a poor prognosis and a high recurrence rate. Since 1980, the median survival of patients with glioblastoma has not increased and remains around 11 months after diagnosis [3]. The lack of efficiency of conventional therapeutic approaches is related to drug-delivery challenges inherent to chemoresistance. New therapeutic strategies directed against tumor vasculature or preventing angiogenesis have been developed with exciting preliminary results [4-5]. The Bevacizumab and other antiangiogenic drugs are likely to play a key role in the treatment of malignant glioma, mostly in association with other molecularly targeted compounds or with cytotoxic molecules [3, 6].

In clinic, the current standard for assessing the efficacy of an anti-tumor therapy is the "Response Evaluation Criteria in Solid Tumor" (RECIST) which is mainly based on measuring tumor volume from radiographic images [7]. Given the observed delay between treatment onset and its effect on tumor size (several weeks or months), an early biomarker of response to therapy would allow rapid treatment adaptation or guide treatment combination, on an individual basis. These biomarkers can arise from biochemical assays (e.g. tissular or circulant markers) or from imaging modalities [8-9].

Among all imaging modalities, magnetic resonance imaging (MRI) appears as a good candidate for monitoring the effect of anti-tumor therapy. MRI is routinely used to estimate tumor volume using anatomical images, but also tumor associated edema and tumor cellularity, using the apparent diffusion coefficient (ADC) of water [10-12]. Moreover, numerous microvascular parameters that appear well-suited to assess the effect of antiangiogenic drugs can be estimated using MRI, such as blood volume, blood flow, microvessel diameter, or vessel wall permeability [13-15]. A recent example shows that the extent of vascular normalization measured by MRI would be predictive of the outcome of anti-Vascular Endothelial Growth Factor (anti-VEGF) therapy in glioblastomes [16].

Several studies have monitored one or two of these parameters to follow the effect of an anti-tumor therapy in addition to RECIST [17-19]. Very few therapeutic follow-up have used an MRI protocol combining more than three parameters [20]. The aim of this study was to analyze various MR parameters into one protocol to assess the impact of 2 different treatments on glioma model and to evaluate if these parameters are relevant, i.e. sensitive to a given treatment.

To address this issue, we used a combined MRI / histology protocol to monitor the effect of a cytotoxic therapy (Carmustin / BCNU; an alkylating agent) and of an antiangiogenic therapy (Sorafenib; Nexavar<sup>®</sup>; a multikinase inhibitor) on U-87 MG, a human glioma model in *Nude* rat. Before and three time points after treatment onset, the following MRI parameters were estimated: tumor volume, water ADC, blood volume fraction (BVf), vessel diameter (vessel size index, VSI), and vessel wall integrity (contrast enhancement, CE). The effect of treatments on each of these MRI parameters was assessed and compared to cellular and vascular characteristics described by immunohistochemistry.

## **Material and methods**

### **Glioma cell line and anti-tumor drugs**

The U-87 MG human glioblastoma cell line was purchased from the American Type Culture Collection (Manassas, VA). Cells were cultured in RPMI1640 medium containing 10% fetal calf serum and 2 mM glutamine.

Sorafenib (Nexavar<sup>®</sup>) was purchased from Bayer Corporation (West Haven, CT, U.S.A) and prepared as a suspension in a mixture of 5% dimethyl sulfoxide (DMSO), 5% tween-20 and 90% NaCl 0.9%.

Carmustine (1,3-bis(2-chloroethyl)-1-nitroso-urea, BCNU) was purchased from Sigma-Aldrich (St. Louis, MO, USA) and dissolved in NaCl 0.9% containing 30% of ethanol.

### ***In vivo* intracerebral U-87 MG glioma model and treatments**

This study was approved by the local committee for animal care and use (approval 081). Experiments were performed under permits n° A380521, A3851610004 and B3851610003 from the French Ministry of Agriculture. Experimental design of this study is presented in figure 1.

Male RH-*rnu/rnu* Nude rats (n=60, weight at arrival: 180-220g, Harlan Sprague Dawley, Indianapolis, USA) were prepared for xenograft by whole body irradiation with a <sup>60</sup>Co  $\gamma$ -source (7 Gy), 24-48 h prior to human tumor cell inoculation. Animals were anesthetized with an intraperitoneal injection of Ketamine (75 mg/kg, Ketamine500<sup>®</sup>, Centravet, France) and Xylazine (5 mg/kg, Rompun<sup>®</sup>, Centravet, France) in 0.9% NaCl solution and immobilized in a stereotactic frame (David Kopf Instrument, Germany). Five  $\mu$ l of U-87 MG cell suspension in serum-free RPMI1640 medium containing 10<sup>5</sup> tumor cells were inoculated in the right caudate nucleus of

the rat brain by stereotactic injection through a 1-mm burr hole at 2.5 mm lateral to the bregma and at a depth of 4.5 mm from the dura. The injection was performed slowly over 15 minutes, and the needle was withdrawn over another 5 minutes. The burr hole was filled with bone wax to prevent extracerebral extension of the tumor (Fig. 1).

Eleven days after tumor implantation (D11), anatomical imaging ( $T_2$ -weighted anatomical images) was performed to evaluate the volume of each tumor. Rats were then randomized and stratified in 3 groups (n=20 per group) with the similar average tumor volume per group (mean tumor volume across all rats at D11,  $3.8 \pm 2.2 \text{ mm}^3$ ). Treatment began 14 days after tumor implantation (Fig. 1; D14<sub>(T0)</sub>):

- BCNU group received two intravenous injections of BCNU ( $10 \text{ mg.kg}^{-1}$ ) the first and the 13<sup>th</sup> days after treatment onset (D14<sub>(T0)</sub> and D27<sub>(T13)</sub>).
- SORA group received daily oral administration of Sorafenib ( $100 \text{ mg.kg}^{-1}$ ) between the 1<sup>st</sup> and 14<sup>th</sup> day after treatment start (D14<sub>(T0)</sub> to D28<sub>(T14)</sub>).
- Untreated group received no treatment.

### ***In vivo* MRI experiments**

Experiments were performed on a horizontal 2.35 Tesla (40 cm diameter) magnet equipped with actively shielded gradient coils (Magnex Scientific Ltd., Oxford, UK) and interfaced to a SMIS console (SMIS Ltd, Guildford, UK). MR acquisitions were performed under anesthesia: 5% isoflurane for induction and 2% for maintenance in 70% air / 30% oxygen. Rectal temperature was maintained at  $37.0 \pm 0.5^\circ\text{C}$  throughout the experiments. After anesthesia, the tail vein was equipped with a catheter allowing injection of contrast agent when the rat lies inside the magnet.

Tumor volume, ADC, BVf, VSI and CE were mapped in tumor and contralateral hemisphere one day before and 1, 4 and 14 days after treatment onset (Fig. 1; D13<sub>(T-1)</sub>, D15<sub>(T1)</sub>, D18<sub>(T4)</sub> and D28<sub>(T14)</sub>, respectively). The last time point was chosen so that it corresponds to 3 days before the median survival time of untreated *Nude* rats bearing U-87 MG glioblastoma (31 days; based on historical data). The total duration of one MRI session was 1h30 per animal. MRI sequences were as follows:

- Anatomical T<sub>2</sub>-weighted images were acquired using a spin-echo MRI sequence (TR/TE = 2000/80 ms, 19 slices with FOV = 30 mm and voxel size = 117x156x1000 μm<sup>3</sup>). Imaging time was 4 min and 17 s.
- ADC was computed from 3 diffusion weighted spin-echo images (in X, Y, and Z directions) with b = 900 s.mm<sup>-2</sup> and a reference image (b ≈ 0 s.mm<sup>-2</sup>) (voxel size = 234x454x1000 μm<sup>3</sup>). Imaging time was 17 min.
- BVf and VSI were estimated using a multi gradient echo and spin-echo MRI sequence (MGESE) (TR = 6 s, 7 evenly spaced gradient-echoes = [6-42] ms, 1 spin-echo = 102 ms, voxel size = 234x454x1000 μm<sup>3</sup>). Imaging time was 13 min and 40 s. MGESE sequences were acquired prior to and 3 min after administration of ultra small superparamagnetic iron oxide (USPIO) via the tail vein within about 20 sec (200 μmoles of iron/kg body weight) (Sinerem<sup>®</sup>, Guerbet, Roissy, France; Combidex<sup>®</sup>, AMAG Pharmaceuticals, Inc, MA, USA). Sinerem<sup>®</sup> is a dextran-coated iron-based contrast agent of about 20 nm in size and 4.5 hours plasmatic half-life in rats at this dose. The relaxivities of Sinerem<sup>®</sup> in water at 2.35T and 37°C are 8 and 89 s<sup>-1</sup>.mM<sup>-1</sup> for r<sub>1</sub> and r<sub>2</sub> respectively (data provided by Guerbet).

- CE was assessed using T<sub>1</sub>-weighted anatomical images acquired using a 3D-MDEFT sequence (voxel size = 333x333x333 μm<sup>3</sup>, TI = 605 ms, alpha = 22°;

TR/TE = 15/5 ms). Imaging time was 4 min and 15 s. To limit the duration of the MR session per animal, a simple subtraction approach was preferred to a dynamic contrast enhanced MRI approach. Thus, one 3D-MDEFT sequence was performed before and 3 min after administration of P846 via the tail vein in about 20 sec (50  $\mu$ moles/kg body weight). P846 (Guerbet, France) is a Gd-based contrast agent with a molecular weight of 3.5 kDa and a plasmatic half-life in rats of  $51.1 \pm 1.1$  min at the concentration used (data provided by Guerbet). The relaxivities of P846, measured in water at 2.35T and 37°C are 28 and 39  $s^{-1}.mM^{-1}$  for  $r_1$  and  $r_2$  respectively (data provided by Guerbet). In this study we used high molecular weight contrast agent (P846: 3.5 kD), instead of the routinely used in clinical (Gd-DOTA or Gd-DTPA: around 0.5 kD), to increase CE sensitivity to different vessel maturity [21].

For each group, 4 rats, called “longitudinal” subgroup were imaged at each time point ( $D13_{(T-1)}$ ,  $D15_{(T1)}$ ,  $D18_{(T4)}$  and  $D28_{(T14)}$ ). After the last MRI measurement, animals were euthanized for subsequent *ex vivo* experiments. Per group the sixteen remaining rats were imaged once and then euthanized at the end of imaging session to enable *ex-vivo* studies (4 animals/time point). They form the “single-time” subgroup (Fig. 1). Due to experimental and technical problems (death of animals due to anesthesia, data unusable because of problems during acquisitions) only 7 out of 8 rats per group yielded acceptable data at  $D13_{(T-1)}$ ,  $D15_{(T1)}$ , and  $D18_{(T4)}$  and only 4 out of 8 rats per group at  $D28_{(T14)}$ . Details of data usable per group (untreated, BCNU and SORA) and subgroup (single-time and longitudinal) were presented in table 1.

### ***Ex vivo* experiments**

At the end of the MRI experiment, the animals were humanely sacrificed (Fig. 1). The brain was quickly removed, frozen in -40°C isopentane and stored at

-80°C until processing. Brains were sliced at -20°C with a cryostat (10 µm thick sections).

First, anatomic changes associated with BCNU and Sorafenib treatment were analyzed using hematoxylin and eosin (HE) staining.

Secondly, vascular components were analyzed by immunohistochemistry of the vessel basal lamina with collagen IV labeling and of endothelial cells using rat endothelial cell antigen-1 labeling (RecA-1). These two stainings allow assessing the impact of anti-tumor treatments on vessel integrity. Slices were rehydrated in phosphate-buffered saline (PBS, 0.01M) and fixed in 4% paraformaldehyde. After saturation in PBS-Tween 0.01%-BSA 3% for 30 min at room temperature, primary antibodies (a goat antibody against collagen IV, Southern Biotech, ref 1340-01, 1/2000; a mouse antibody against RecA-1, AbD Serotec ref. MCA9070R, 1/200) were incubated overnight at 4°C in PBS-Tween 0.01%-BSA 1%. Secondary antibodies were Alexa 546-linked Donkey anti-goat IgG (Invitrogen, A11030, 1/200) and Alexa 488 linked Donkey anti-mouse IgG (Invitrogen, A21202, 1/200).

### **USPIO extravasation**

The MR method used to estimate BVf and VSI uses as a starting hypothesis that the contrast agent remains intravascular [22]. To estimate the amount of USPIO that extravasates during BVf and VSI measurements, dynamic contrast-enhanced MRI (DCE-MRI) was performed on tumor bearing rats (n=12, in addition to those already mentioned). At each time point, the 4 animals of each group (SORA, BCNU and untreated groups) were imaged with multiple  $T_{1w}$  spin-echo images (TR/TE = 600/17ms, voxel size = 234x234x1000 µm<sup>3</sup>, 1 min 17 s/image; 17 repetitions; total acquisition time = 21 min 49s). After one repetition (i.e. 1 min 17s after imaging start), Sinerem<sup>®</sup> was administered as described above.

## Data analysis

Determination of tumor volume: Tumor volume was obtained by manually delineating the tumors on anatomical T<sub>2</sub>-weighted MR images from adjacent slices containing the lesions, counting voxels within the tumor boundaries, and scaling with the voxel volume.

ADC, BVf and VSI: Data were processed as described in Valable et al. [22] using in-house developed software in the Matlab<sup>®</sup> environment. Regions of interest (ROIs) were manually delineated over the tumor on the 3 T<sub>2</sub>-weighted slices containing the largest tumor area. Contralateral ROIs were defined in the contralateral striatum on the same slices. ROIs were transferred on ADC, BVf and VSI maps. Then, within each ROI and each map, voxels for which the analysis could not be performed were identified (e.g. voxels with non-converging fit and voxels with values outside the range of validity of the method (ADC > 3500 μm<sup>2</sup>.s<sup>-1</sup>; BVf > 17%, VSI > 50 μm) and excluded from the analysis. The total number of voxels, the number of excluded voxels, the mean and standard deviation over the 3 analyzed slices for a rat were computed for each ROI and each parameter. Rejected voxels per ROI represented 4.5% for tumor and 0.5% contralateral striatum of the total number of voxels, for all groups.

CE: Vessel integrity was assessed using the T<sub>1w</sub> images acquired before (T<sub>1w(before)</sub>) and 3 min after (T<sub>1w(after)</sub>) injection of P846 as describe by equation 1.

$$CE = \frac{SI(T_{1w(after)}) - SI(T_{1w(before)})}{SI(T_{1w(before)})} \quad \text{equation 1}$$

SI : Signal Intensity

USPIO extravasation: Since DCE-MRI images were acquired with a TE = 17ms, a decrease in signal (due to T<sub>2</sub>\* reduction, intravascular USPIO) was observed just after injection of USPIO, after which, in case of extravasation, signal increased (T<sub>1</sub>

reduction, extravascular USPIO). The relative increase in signal between the first image acquired after USPIO injection and the last image of the DCE-MRI protocol was assigned to  $T_1$  effect. Eventually, this signal enhancement was converted to extravascular iron concentration as described by Valable et al. [22]. Since we neglected the plasmatic clearance of USPIO in our analysis, we overestimated the  $T_1$  effects and thus obtained an upper limit of the extravascular iron concentration.

Quantitative histology: Sections corresponding to MRI images (up to three microscopic fields per ROI and animal) were digitized using a CCD camera (Olympus, Rungis, France). Collagen IV images were binaries and vascular parameters (mean vessel density, fractional vascular surface area, mean vessel radius) were obtained using ImageJ software (Rasband,W.S., ImageJ) as described by Valable et al. [22].

### **Statistical analysis**

Paired t tests were used for comparing tumor versus contralateral striatum inside the same group. Independent t tests were used for comparing data between each group.  $p < 0.05$ : \*;  $p < 0.01$ : \*\* and  $p < 0.001$ : \*\*\*. All statistics were performed with SPSS (SPSS Inc, Chicago, Ill, USA). Results are presented as mean  $\pm$  standard deviation and are given by group, by time point and by region of interest.

# Results

## Accuracy of the BVf and VSI measurements

Using our model, accurate BVf and VSI measurements require that the iron-based contrast agent remains intravascular. At each time point, USPIO extravasation data were not statistically different across all groups (data were thus pooled). In contralateral tissue, iron concentration remained below the detection sensitivity of our DCE-MRI approach ( $\leq 1\mu\text{M}$ ) [22]. Nineteen minutes after USPIO injection (corresponding to the end of MR data acquisition in BVf/VSI measurement), the average iron concentration in the tumor across all groups and time points was  $2.6 \pm 0.4 \mu\text{M}$ . This concentration corresponds to 0.3% of the plasma iron concentration ( $3420 \pm 970 \mu\text{M}$ , data reported by Valable et al. [22]).

## Longitudinal MRI follow-up

In a longitudinal study, repeated anesthesia and contrast agent injections might affect the physiological status of the animal, the rate of tumor growth and the accuracy of the MRI measurements. To check this, we compared for each group the "single-time" and the "longitudinal" subgroups at each time point and we observed no difference in body weight, tumor size, ADC, BVf, VSI and in CE between. In this experiment, a longitudinal study (repetition of MRI protocol) has no effect on the assessed parameters. Consequently, for the 3 groups, values from the "single-time" and "longitudinal" subgroups were pooled at each time-point.

## *In vivo* anti-tumor activity of BCNU and Sorafenib treatments

### *MRI data in contralateral rat brain hemisphere*

No significant difference over time and across the 3 groups in ADC, BVf and VSI was detected contralaterally ( $720 \pm 85 \mu\text{m}^2 \cdot \text{s}^{-1}$ ,  $3.3 \pm 0.5\%$  and  $5.6 \pm 1.1 \mu\text{m}$  for ADC, BVf and VSI mean across time points and groups respectively). Consequently, the mean contralateral value across groups is represented at each time point, for the sake of clarity (Fig. 3; dotted line). However, for comparisons between tumor and contralateral tissue at one time point, statistical analysis was performed using only the contralateral values of each group.

### ***U-87 MG tumor development (untreated group)***

The volume of the untreated U-87 MG tumors increased rapidly between D13<sub>(T-1)</sub> and D28<sub>(T14)</sub> ( $4.5 \pm 1.4$  to  $117.1 \pm 22.9 \text{ mm}^3$  respectively; Fig. 2). ADC, BVf and VSI in U-87 MG tumors were significantly higher than in the contralateral striatum and remained stable with time (tumor:  $851 \pm 43 \mu\text{m}^2 \cdot \text{s}^{-1}$ ,  $4.4 \pm 0.3 \%$  and  $7.9 \pm 1.2 \mu\text{m}$ ; contralateral striatum:  $720 \pm 85 \mu\text{m}^2 \cdot \text{s}^{-1}$ ,  $3.3 \pm 0.5 \%$  and  $5.5 \pm 0.3 \mu\text{m}$  for ADC, BVf and VSI respectively, mean value across the four time points,  $p < 0.001$ ; Fig. 3A-C). In the untreated group, glioma vessels were permeable to P846 during follow-up (CE:  $190 \pm 47 \%$ , mean across all time points; Fig. 3D).

### ***Effect of BCNU on U-87 MG glioma (BCNU group)***

BCNU treatment strongly inhibited tumor growth compared to untreated group ( $5.7 \pm 4.9$  vs.  $117.1 \pm 22.9 \text{ mm}^3$ , for the BCNU and untreated groups respectively, at D28<sub>(T14)</sub>,  $p < 0.001$ ; Fig. 2). Intratumoral ADC was comparable between the BCNU and untreated groups at all time points excepted at D28<sub>(T14)</sub> when ADC in the BCNU group became significantly larger than in the untreated group ( $1048 \pm 10$  vs.  $794 \pm 49 \mu\text{m}^2 \cdot \text{s}^{-1}$ ,  $p < 0.001$ ; Fig. 3A). VSI, BVf and CE in the BCNU group did not differ from those measured in the untreated group (Figs. 3B-D).

### ***Effect of Sorafenib on U-87 MG glioma (SORA group)***

Sorafenib treatment inhibited significantly tumor growth ( $28.7 \pm 11.1$  vs.  $117.1 \pm 22.9 \text{ mm}^3$  for the SORA and untreated groups, respectively, at  $D28_{(T14)}$ ,  $p < 0.001$ ; Fig. 2). At  $D28_{(T14)}$ , ADC in the SORA group was larger than in the untreated group ( $976 \pm 37$  and  $794 \pm 49 \text{ } \mu\text{m}^2 \cdot \text{s}^{-1}$ , respectively,  $p < 0.001$ ; Fig. 3A).

All vascular parameters assessed in this study (VSI, BVf and CE) were modified by Sorafenib. While tumoral VSI in the SORA and untreated groups were similar before treatment ( $D13_{(T-1)}$ ), tumoral VSI in the SORA group became significantly larger than in the untreated group as early as  $D18_{(T4)}$  and up to  $D28_{(T14)}$  ( $D18_{(T4)}$  :  $7.2 \pm 1.8$  vs  $5.8 \pm 1.8 \text{ } \mu\text{m}$ ;  $p < 0.001$  and  $D28_{(T14)}$  :  $12.4 \pm 1.7$  vs  $8.7 \pm 1.7 \text{ } \mu\text{m}$ ;  $p < 0.01$ , respectively; Fig 3B). In the SORA group, the tumoral BVf decreased from treatment onset ( $D15_{(T1)}$ :  $5.0 \pm 0.8$  to  $D28_{(T14)}$ :  $2.6 \pm 1 \%$ ; Fig. 3C) while it remained stable in the untreated group ( $D15_{(T1)}$ :  $5.2 \pm 0.9$  to  $D28_{(T14)}$ :  $5.5 \pm 0.8 \%$ ; Fig. 3C). In contrast to what happens in untreated and BCNU group, in the SORA group the extravasation of P846 was significantly reduced as early as 1 day after Sorafenib treatment start (CE:  $116 \pm 65\%$  vs  $184 \pm 42\%$  for the SORA and untreated groups respectively at  $D15_{(T1)}$ ) and was not detectable at  $D28_{(T14)}$  (Fig. 3D).

## HE staining

From  $D13_{(T-1)}$  to  $D18_{(T4)}$ , U-87 MG tumors in the untreated, BCNU and SORA groups presented very similar anatomical histological structures on HE stained sections. Cell density was higher in the tumor core with some tumor cells aligned along vessels, forming thin bundles. Tumors were surrounded by a ring of highly edematous tissue. Neither necrosis nor pseudo-cyst was observed (Fig. 4). At  $D28_{(T14)}$ , in the SORA and BCNU groups tumor cell density was reduced compared to previous time points and edematous areas appeared inside the tumor tissue (Fig. 4).

## Vascular staining

To assess variation in vasculature properties, collagen IV and RecA labelings were performed (Fig. 4). For all groups and all time points, vessels in contralateral striatum exhibited similar diameter, density and vascular surface area ( $4.4 \pm 0.2 \mu\text{m}$ ,  $337 \pm 37$  vessels per  $\text{mm}^2$  and  $3.76 \pm 0.34$  % vascular surface area; mean across all groups and all time points; table 2). All vessels were also stained by Collagen IV and RecA (Fig. 4). Before treatments, in all groups, tumor vessels diameter were higher than in the contralateral striatum ( $5.2 \pm 0.6$ ;  $5.4 \pm 0.6$  and  $6 \pm 0.3 \mu\text{m}$  versus  $4.2 \pm 0.2 \mu\text{m}$  for untreated, BCNU and SORA groups versus mean of contralateral striatum across all group, respectively;  $p < 0.05$ ; table 2) and vascular surface area was higher than in contralateral striatum ( $9.1 \pm 1.4$ ;  $6.2 \pm 1.3$  and  $7.7 \pm 0.3$  % versus  $3.7 \pm 0.5$  % for untreated, BCNU and SORA groups versus mean of contralateral striatum across all group, respectively;  $p < 0.05$ ; table 2). To 3 time points after treatment no change in vascular parameters was observed in untreated and BCNU groups.

At D28<sub>(T14)</sub>, in the SORA group, tumor vessel density decreased as compared to untreated group ( $141 \pm 21$  versus  $301 \pm 60$  vessels per  $\text{mm}^2$  respectively;  $p < 0.01$ ) and vascular area was similar to that in contralateral striatum ( $3.7 \pm 1.4$  versus  $3.7 \pm 0.3$  %, respectively;  $p = 0.45$ ; table 2) but vessel diameter was higher than in contralateral striatum ( $5.8 \pm 0.7$  versus  $4.2 \pm 0.1$  vessels per  $\text{mm}^2$ , respectively;  $p < 0.05$ ; table 2). Finally, only a fraction of the tumor vessels stained by Collagen IV antibody was also stained by RecA antibody (Fig. 4).

## Discussion

The effect of two different treatments (BCNU, an alkylating agent and Sorafenib, a multikinases inhibitor) on an orthotopic human glioblastoma model (U-87 MG) xenografted in *Nude* rats was investigated by MRI and by immunohistology. MRI highlighted an important inhibition of tumor growth induced by both Sorafenib and BCNU treatments. As previously demonstrated, ADC, BVf and VSI values were higher in the tumor tissue than in the contralateral striatum. Sorafenib treatment induced significant differences firstly on tumor contrast enhancement ( $D13_{(T-1)}$ ), then on BVf and VSI ( $D18_{(T4)}$ ) and finally on ADC and tumor size ( $D28_{(T14)}$ ) compared to control animals. In the BCNU group, only tumor size and ADC were modified 14 days after treatment onset.

As a first prerequisite of this study, we determined whether our extensive MR protocol could be repeated to monitor therapy response on brain tumor. First, we compared for each group the “single-time” and the “longitudinal” subgroups. In each “longitudinal” subgroup neither repeated anesthesia, repeated injection of contrast agent, nor treatment (BCNU or Sorafenib) had any detectable effect on body weight (data not shown), on tumor volume nor on MR-determined parameters as compared to the “single-time” subgroup. The second prerequisite was to assess whether the USPIO extravasated in this tumor model within the time frame of the MR session. A separate experiment, performed on 4 animals per group followed at each time point ( $D13_{(T-1)}$ ,  $D15_{(T1)}$ ,  $D18_{(T4)}$  and  $D28_{(T14)}$ ) showed that the extravascular concentration of USPIO in the tumor was at most 0.3% of the plasmatic concentration 20 min after injection. This result validates the main hypothesis of the VSI and BVf measure, considering the USPIO as an intravascular contrast agent. Moreover, it showed that the complete imaging protocol could fit within approximately 90 minutes, which

allows designing follow-up experiments with a sufficient number of animals per group. All these results indicate that our experimental protocol was appropriate to monitor the effect of anti-tumoral therapies in our U-87 MG tumor model.

The goal of this study was to assess the sensitivity of multiparametric MRI to monitor the anti-tumor activity of BCNU and Sorafenib.

ADC in tumor was increased by both treatments compared to the untreated group 14 days after treatment onset. This increase is consistent with the cytotoxic effect of BCNU and the ADC is also known to be affected by changes in cell density (or cellularity) [23] and by the occurrence of vasogenic edema. HE staining showed that cell density was smaller in the tumors of treated groups than in the untreated group 14 days after treatment onset. HE staining also showed intratumoral edema in treated groups. Even if the mechanisms involved in ADC changes are complex, these histological findings could explain the increase in intratumoral ADC in BCNU and SORA groups observed 14 days after treatment onset.

Tumor microvasculature properties assessed by both MRI and histology were not changed by the BCNU treatment. Conversely, Sorafenib induced significant modifications in tumor microvasculature. Four days after antiangiogenic treatment onset, the mean intratumoral BVf was markedly reduced in comparison with the untreated group and was close to its normal value. This result suggests a tendency towards normalization of tumor vasculature: under antiangiogenic treatment, the tumor vasculature becomes more similar to healthy tissue. However, at the same time point (D18<sub>(T4)</sub>), tumoral VSI was increased by Sorafenib, with values higher than that observed in animals of untreated group. The quantitative immunohistochemistry of tumor vessels confirmed these observations on vessels diameter and also

indicated that the vessel density was decreased. The decrease of vessels density observed in immunohistochemistry is consistent with the decrease of BVf and the concomitant increase in vessels diameter observed by MRI. In addition to these morphological changes, 1 day after the start of Sorafenib treatment (D15<sub>(T1)</sub>), immunohistochemistry showed some collagen IV-positive vessels without RecA labeling. These observations indicate that some tumor vessels are formed only with basal lamina. This discrepancy between both labelings was even more pronounced after 4 and 14 days of treatment. This has been previously reported in several studies [24-25]. Inai et al. observed collagen IV-positive vessels without endothelial marker in spontaneous pancreatic islet tumors treated with a VEGFRs inhibitor.

We also observed a decrease of tumors contrast enhancement as soon as 1 day after antiangiogenic treatment onset. This reduction was more pronounced 4 days after treatment onset and no P846 contrast agent extravasation was detectable 14 days after treatment beginning. BVf and VSI estimates using an intravascular contrast agent (USPIO) injection argue for perfusion from at least part of tumoral vessels under antiangiogenic treatment. These differential BBB permeability between contrast agents who exhibit different size has already been described in the study of Turetschek et al. [26]. Together these results could indicate that the absence of contrast enhancement of tumors after 14 days of Sorafenib treatment is due to modifications of vessel permeability and not due to a lack of tumor perfusion. Modifications of vessels integrity observed in our study are consistent with results of Flaherty et al. who observed by MRI a decrease in vessel permeability/perfusion ( $K_{trans}$ ) after 3-12 weeks of Sorafenib treatment in patients bearing a renal cell carcinoma [17].

In our study BVf and CE parameters indicated a normalization of tumoral vessels under antiangiogenic treatment, which has already been described in several studies [20, 27]. In addition to these two MR parameters, estimates of VSI indicate that tumor vessels had abnormal size compared to vessels in healthy tissue. A normalization of vascular permeability/perfusion associated to an increase in vessel diameters under antiangiogenic treatment has already been described [28]. These results highlight the necessity to measure together VSI, BVf and CE parameters to monitor the different aspects of tumor microvasculature under antiangiogenic treatment. An important step in future studies will be to demonstrate that all the MR parameters used to evaluate the impact of anti-tumoral treatments are independent of each other. After this demonstration we could relate, using multivariate statistical methods, MR parameters with animal survival or tumor progression as proposed by Sorensen et al. with 2 MR parameters plus one biological measurement associated with patient outcome [16].

Glioblastomas are tumors highly resistant to many types of treatment. Monotherapies with antiangiogenic or cytotoxic drugs, like Sorafenib and BCNU respectively, demonstrated moderate efficacy in glioblastomas in preclinical models (Onco*design* Biotechnology internal data). MRI biomarkers reveal that drugs effectively fight their target and eventually induce both morphological and physiological changes for which drugs are design. This would be helpful for pharmacological drug treatments optimization or combination.

The multiparametric MRI approach described in this study allowed measuring various characteristics of cellular and vascular remodeling that occurs under therapy. To further complete this characterization, additional MRI developments can be foreseen or refined analysis could be evaluated. In our study we use a CE-MRI

technical to evaluate vessel wall integrity, but this parameter depends on blood flow, vessel wall permeability and diffusion of contrast agent into the extravascular compartment. A dynamic CE-MRI approach with an appropriate data modeling [29-30] could be used to quantify and possibly differentiate the change in vascular permeability and blood flow. But to apply this quantitative approach, we need to optimize our protocol to allow measurements of VSI, BVf (using USPIO) and permeability/perfusion (using gad-based contrast agent) in a same MRI session [31]. Blood flow could also be obtained using Dynamic Susceptibility Contrast MRI or Arterial Spin Labeling [32]. Using a quantitative analysis of  $T_2^*$  decay [33], one could estimate the oxygen extraction fraction in the tumor, a possible marker of tumor hypoxia.

In conclusion, this study indicates that numerous changes occur in the tumor microvasculature and cellularity after antiangiogenic or cytotoxic therapy. This study also indicates that the sensitivity of the studied MR parameters varies for a given treatment and is also treatment dependent. Moreover, these changes appear complex and may not be summarized by a single physiological measurement. MRI appears as an imaging modality that can follow, non-invasively, several microvascular and cellular parameters with a strong potential for the evaluation of new drugs on brain tumors. In addition, they could provide methods to better describe and understand the mechanisms of action of antiangiogenic or antivascular therapies, allowing the rational design of optimized combinations with chemotherapies and/or radiotherapies.

Table 2: Quantitative immunohistology of collagen IV staining of each group (untreated, BCNU and SORA) and each time point (D13<sub>(T-1)</sub>, D15<sub>(T1)</sub>, D18<sub>(T4)</sub> and D28<sub>(T14)</sub>). In contralateral striatum data from all groups were pooled.

## Legends

Figure 1. Experimental protocol. At D0 60 rats were orthotopically implanted with  $10^5$  U-87 MG glioma cells. Eleven day later (D11) animals were randomized and stratified in 3 groups (n=20 per group) with similar mean tumor volume (using anatomical images). BCNU group received two intravenous injections of BCNU the first and the 13<sup>th</sup> days after treatment onset (D14<sub>(T0)</sub> and D27<sub>(T13)</sub>). SORA group received daily oral administration of Sorafenib between the 1<sup>st</sup> and 14<sup>th</sup> day after treatment beginning (D14<sub>(T0)</sub> to D28<sub>(T14)</sub>). Untreated group received no treatment. For each group, 4 rats, called “longitudinal” subgroup were imaged at each time point (D13<sub>(T-1)</sub>, D15<sub>(T1)</sub>, D18<sub>(T4)</sub> and D28<sub>(T14)</sub>). After the last MRI measurement, animals were euthanized for subsequent *ex vivo* experiments. Per group the sixteen remaining rats, called “single-time” subgroup, were imaged once and then euthanized at the end of imaging session to enable *ex-vivo* studies (4 animals/time point).

Figure 2. Tumor volumes for untreated, BCNU and SORA groups assessed by MRI as function of time. Mean  $\pm$  SD.  $p < 0.001$ : \*\*\*, untreated versus SORA group;  $p < 0.001$ : \$\$\$; untreated versus BCNU group.

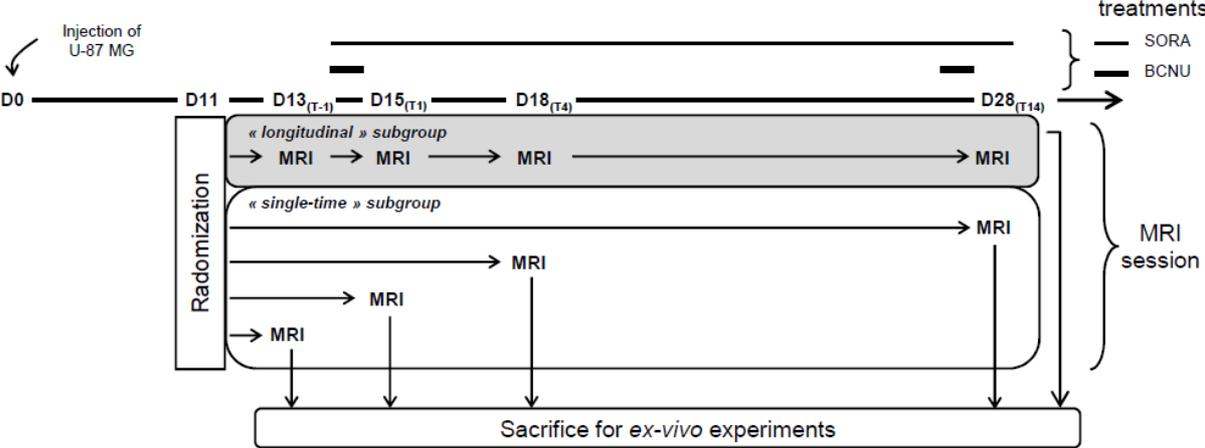

Figure 3. *In vivo* MRI estimated parameters. (A) Evolution of ADC, (B) microvessel diameter (VSI), (C) blood volume fraction (BVf) and (D) vessel permeability (CE-MRI) as function of time across each group. A representative map and the averaged value for group analysis are shown for each parameter and for each group at each time point. Dotted lines on MRI maps represent tumor ROI determinate on anatomical

images. Mean  $\pm$  SD.  $p < 0.05$ : \*,  $p < 0.01$ : \*\*,  $p < 0.001$ : \*\*\*, untreated versus SORA group;  $p < 0.001$ : \$\$\$; untreated versus BCNU group.

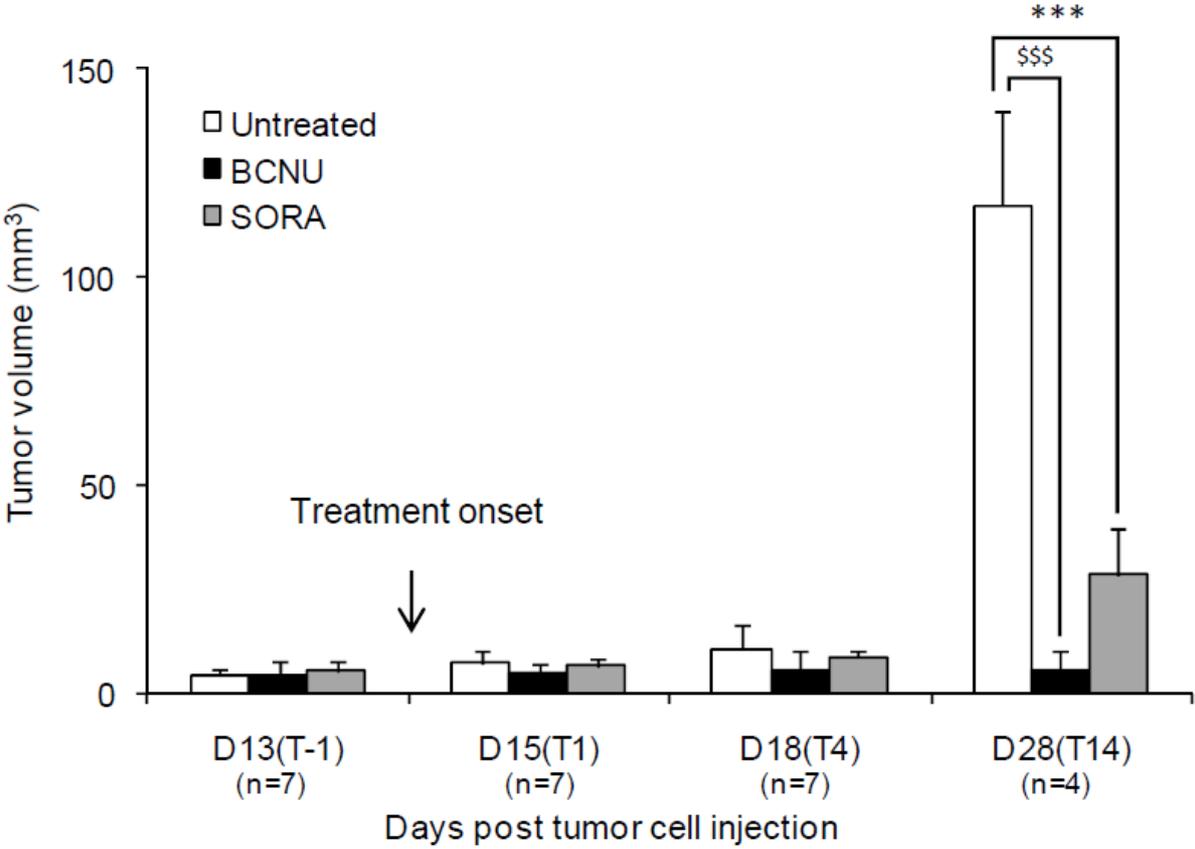

Figure 4. Histological and immunohistological images at D28<sub>(T14)</sub>. Example of hematoxylin/eosine (HE) staining representative of contralateral and intratumoral tissue in the untreated, BCNU and SORA groups. Black arrows point to the hypostained intratumoral edema. Collagen IV and RecA stainings representative of contralateral striatum and of tumor region for each group. White arrows point to intratumoral vessel only stained by collagen IV in SORA group. Scale bar = 100  $\mu$ m.
