Abstract

The gut microbiome is the ensemble of microorganisms that inhabit the gastrointestinal tract. A dynamic host-microbiome symbiosis exists in the intestine and specific interactions between the microbiota and host metabolism and immune system are critical for shaping host physiology. Disturbance of this symbiosis has been hypothesized to play a role in the development of various chronic diseases, including colorectal cancer. Indeed, there is growing experimental evidence that the gut microbiome potentially influences tumor development through dysregulation of host metabolism and immune function. However, epidemiological data linking the gut microbiome with colorectal carcinogenesis remains limited as very few existing cohorts have collected fecal samples. Colorectal cancer screening programs, in which millions of stool samples are collected each year, might provide rich opportunities to establish population-based cohorts with repeated, prospectively collected samples.

The first part of the thesis systematically summarizes the current epidemiological literature that has been published in the past decade on the association of the human microbiome with cancer. Our findings emphasised that for most microbiome indicators, the evidence was still too weak to draw firm conclusions in relation to their role in cancer.

The second part of the thesis investigates the association between insulin resistance and inflammation - recognised colorectal cancer risk factors - and the gut microbiome in two population-based cohorts – the Northern Finland Birth Cohort and TwinsUK. Our study indicated that higher levels of insulin resistance and other markers of metabolic dysfunction were associated with lower microbiome diversity in both cohorts, even after control for obesity and other factors.

Finally, the third part of the thesis evaluates microbiome stability and accuracy in fecal samples collected using different methods employed in ongoing colorectal cancer screening programs. Our findings suggest that commonly used fecal sample collections such as fecal immunotests and paper-based collection cards are, in general, suitable media for microbiome measurements though storage factors such as ambient temperature can impact on stability for some methods. In addition, the

opportunistic collection of fecal samples in fecal immunochemical test tubes after colorectal cancer screening is likely a viable method for establishing cohorts with prediagnostic fecal specimens.

Overall, this thesis presents the state-of-the-art on epidemiological evidence for the role of the microbiome in tumorigenesis, provides novel insights on the association of metabolic risk factors for colorectal cancer with the gut microbiome in population-based studies, and finally has generated important methodological data on the impact of fecal sample collection tools on microbial measurements that is needed for future epidemiological research on the microbiome and colorectal cancer, as well as other chronic diseases.

Résumé

Le microbiome intestinal désigne l'ensemble des micro-organismes présents dans le tractus gastro-intestinal. Une symbiose dynamique entre l'hôte et le microbiome existe dans l'intestin et des interactions spécifiques entre le microbiome et le métabolisme de l'hôte, et son système immunitaire, sont essentielles pour façonner la physiologie de l'hôte. L'hypothèse que la perturbation de cette symbiose joue un rôle dans le développement de diverses maladies chroniques, y compris du cancer colorectal, a été émise. En effet, il existe de plus en plus de preuves expérimentales selon lesquelles le microbiome intestinal influence potentiellement le développement de tumeurs par le biais d'une dérégulation du métabolisme de l'hôte et de sa fonction immunitaire. Cependant, les données épidémiologiques reliant le microbiome intestinal à la carcinogenèse colorectale restent limitées car très peu de cohortes existantes ont collecté des échantillons fécaux. Les programmes de dépistage du cancer colorectal, dans lesquels des millions d'échantillons de selles sont prélevés chaque année, pourraient fournir de riches opportunités pour établir des cohortes basées sur la population avec des échantillons répétés et prospectivement collectés.

La première partie de la thèse résume de manière systématique la littérature épidémiologique actuelle qui a été publiée au cours de la dernière décennie sur l'association entre le microbiome et le cancer. Nos résultats ont souligné que pour la plupart des indicateurs du microbiome, les preuves étaient encore trop faibles pour tirer des conclusions définitives concernant leur rôle dans le cancer.

La deuxième partie de la thèse étudie l'association entre la résistance à l'insuline et l'inflammation - des facteurs de risque reconnus du cancer colorectal - et le microbiome intestinal, dans deux cohortes populationnelles : The Northern Finland Birth Cohort et TwinsUK. Notre étude a indiqué que des niveaux plus élevés de résistance à l'insuline et d'autres marqueurs de dysfonctionnement métabolique étaient associés à une diversité amoindrie du microbiome dans les deux cohortes, même après contrôle de l'obésité et d'autres facteurs.

Enfin, la troisième partie de la thèse évalue la stabilité et la concordance du microbiome dans les échantillons fécaux prélevés à l'aide de différentes méthodes

utilisées dans les programmes de dépistage du cancer colorectal en cours. Nos résultats suggèrent que les collections d'échantillons fécaux couramment utilisées, telles que les tests immunochimiques fécaux et les cartes de prélèvement sur papier, sont en général des supports appropriés pour mesurer la diversité microbiome, bien que des facteurs de stockage, tels que la température ambiante, puissent avoir un impact sur la stabilité de certaines méthodes. En outre, la collecte opportuniste d'échantillons fécaux dans des tubes à tests immunochimiques fécaux après le dépistage du cancer colorectal est probablement une méthode viable pour établir des cohortes avec des échantillons fécaux pré-diagnostic.

Dans l'ensemble, cette thèse présente l'état de l'art sur les preuves épidémiologiques du rôle du microbiome dans la tumorigenèse. Elle fournit de nouvelles informations sur l'association des facteurs de risque métaboliques du cancer colorectal avec le microbiome intestinal dans les études populationnelles. Enfin, elle a généré d'importantes données méthodologiques sur l'impact des outils de collecte d'échantillons fécaux sur les mesures microbiennes nécessaires pour les futures recherches épidémiologiques sur le microbiome et le cancer colorectal, ainsi que sur d'autres maladies chroniques.

Résumé substantiel

Le microbiome intestinal désigne l'ensemble des micro-organismes, incluant les bactéries commensales et pathogènes, les virus, les archées et les mycètes, ainsi que leur matériel génétique présents dans le tractus gastro-intestinal. Le microbiome intestinal possède de nombreuses fonctions métaboliques, telles que la production d'acides gras à chaîne courte via la fermentation de polysaccharides complexes, la déconjugaison d'acides biliaires, la synthèse de lipopolysaccharides spécifiques et la biosynthèse de certains acides aminés essentiels et vitamines. Une symbiose dynamique entre l'hôte et le microbiome existe dans l'intestin et des interactions spécifiques, telles que la digestion d'aliments et l'extraction de nutriments ou le métabolisme de certains médicaments, entre le microbiome et le métabolisme de l'hôte, et son système immunitaire, sont essentielles pour façonner la physiologie de l'hôte. Cependant, cette symbiose repose sur un équilibre fragile, et des perturbations des interactions entre l'hôte et le microbiome intestinal ont été associées à plusieurs maladies chroniques telles que l'obésité, le diabète et potentiellement différents types de cancer.

Le cancer colorectal est le troisième cancer le plus fréquent chez les hommes et le deuxième chez les femmes, et est également la deuxième cause de décès par cancer dans le monde chez les deux sexes combinés. Bien que les facteurs génétiques, tel que les antécédents familiaux de cancer colorectal, ainsi que l'inflammation chronique induite par les maladies inflammatoires de l'intestin, contribuent au développement du cancer colorectal, il existe des preuves indiquant que de nombreux facteurs modifiables liés à l'alimentation et au mode de vie affectent le risque de cancer colorectal. De plus en plus d'indices suggèrent que le microbiome intestinal influence potentiellement l'initiation et la progression du développement tumoral par le biais d'une dérégulation du métabolisme de l'hôte et de sa fonction immunitaire, ainsi que par des perturbations des processus homéostatiques favorisant l'inflammation chronique et l'instabilité du génome induisant des mutations.

Le lien potentiel entre le microbiome intestinal et la néoplasie colorectale représente une hypothèse prometteuse pour étudier les caractéristiques inexplicées du cancer colorectal. Cependant, les données épidémiologiques reliant le microbiome intestinal

à la carcinogenèse colorectale restent limitées car très peu de cohortes existantes ont collecté des échantillons fécaux. Les données basées sur des études cas-témoins ne permettent pas de déterminer si le processus de cancérogenèse modifie l'environnement local et crée une nouvelle niche pour les micro-organismes, ou si les altérations de la population microbienne contribuent à la cancérogenèse. Des échantillons répétés, collectés prospectivement à partir d'études de cohortes populationnelles, sont donc nécessaires pour une meilleure compréhension de la temporalité des associations microbiennes avec le cancer colorectal. Les programmes de dépistage du cancer colorectal, dans lesquels des millions d'échantillons de selles sont prélevés chaque année, pourraient fournir de riches opportunités pour établir des cohortes basées sur la population avec des échantillons répétés et collectés prospectivement.

L'objectif de cette thèse est de contribuer à déchiffrer les associations supposées entre le microbiome intestinal et le développement du cancer colorectal en renforçant les preuves épidémiologiques sur la relation entre le microbiome intestinal et des facteurs de risque établis de cancer colorectal, notamment la résistance à l'insuline et l'inflammation chronique, ainsi qu'en évaluant des méthodes de collection d'échantillons de matières fécales utilisées dans les programmes de dépistage.

La première partie de la thèse résume de manière systématique la littérature épidémiologique actuelle qui a été publiée au cours de la dernière décennie sur l'association entre le microbiome et le cancer. En effet, si certaines revues et méta-analyses portant sur les profils de microbiome en lien avec des cancers spécifiques ont déjà été publiées, aucun aperçu systématique des associations les plus significatives entre la composition du microbiome (par exemple les taxons et la diversité) et les différents sites de cancer n'a été publié à ce jour. En raison de la diversité des données publiées, un aperçu des preuves épidémiologiques disponibles liant le microbiome au cancer est nécessaire.

Nos résultats indiquent que bien que des preuves soient disponibles pour le lien entre certains taxons du microbiome intestinal et le risque de cancer colorectal, et pour le microbiome buccal et le risque de cancer buccal, pour la plupart des indicateurs du microbiome, les preuves sont encore trop faibles pour tirer des conclusions définitives

concernant leur rôle dans le cancer. La plupart des preuves nécessitent une validation dans des études prospectives basées sur la population.

La deuxième partie de la thèse étudie l'association entre la résistance à l'insuline et l'inflammation - des facteurs de risque reconnus du cancer colorectal - et le microbiome intestinal, dans deux cohortes populationnelles : The Northern Finland Birth Cohort et TwinsUK. Alors que l'hypothèse selon laquelle le microbiome intestinal influence le développement de la résistance à l'insuline a été émise, les données humaines sur la résistance à l'insuline et d'autres paramètres métaboliques et le microbiome intestinal sont encore limitées, car très peu de cohortes ont collecté des échantillons sanguins et fécaux. La résistance à l'insuline est une cause potentielle du diabète et d'autres maladies métaboliques, et constitue un facteur de risque établi de cancer colorectal. Par conséquent, déchiffrer la physiopathologie de la résistance à l'insuline à l'aide de données populationnelles pourrait aider à comprendre les mécanismes de développement du cancer colorectal et à renforcer les preuves de stratégies préventives potentielles.

Notre étude a indiqué que des niveaux plus élevés de résistance à l'insuline et d'autres marqueurs de dysfonctionnement métabolique étaient associés à une diversité amoindrie du microbiome dans les deux cohortes, même après contrôle de l'obésité et d'autres facteurs. Cependant, en raison de la nature transversale de cette étude, il est impossible de conclure si ces différences dans la composition du microbiome et les associations de taxons sont une cause ou une conséquence d'un dysfonctionnement métabolique.

Enfin, la troisième partie de la thèse évalue la stabilité et la concordance du microbiome dans les échantillons fécaux prélevés à l'aide de différentes méthodes utilisées dans les programmes de dépistage du cancer colorectal en cours dans différents pays. En effet, pour potentiellement conseiller l'établissement d'études internationales ayant des échantillons fécaux répétés et collectés prospectivement basés sur des programmes de dépistage du cancer colorectal, un travail méthodologique est nécessaire pour tester les tubes de test immunochimique fécal et les cartes de prélèvement d'échantillons utilisées dans les pays où différents dispositifs de dépistage sont utilisés.

Nos résultats suggèrent que les collections d'échantillons fécaux couramment utilisées, telles que les tests immunochimiques fécaux et les cartes de prélèvement sur papier, sont en général des supports appropriés pour mesurer la diversité microbiome, bien que des facteurs de stockage, tels que la température ambiante, puissent avoir un impact sur la stabilité de certaines méthodes. En outre, la collecte opportuniste d'échantillons fécaux dans des tubes à tests immunochimiques fécaux après le dépistage du cancer colorectal est probablement une méthode viable pour établir des cohortes avec des échantillons fécaux pré-diagnostic.

Dans l'ensemble, cette thèse présente l'état de l'art sur les preuves épidémiologiques du rôle du microbiome dans la tumorigenèse. Elle fournit de nouvelles informations sur l'association des facteurs de risque métaboliques du cancer colorectal avec le microbiome intestinal dans les études populationnelles. Enfin, elle a généré d'importantes données méthodologiques sur l'impact des outils de collecte d'échantillons fécaux sur les mesures microbiennes nécessaires pour les futures recherches épidémiologiques sur le microbiome et le cancer colorectal, ainsi que sur d'autres maladies chroniques.

Chapter I: Introduction

1. The human gut microbiome

1.1. General information on the human gut microbiome

1.1.1. Definitions

The rapid evolution of the microbiomics field has been accompanied by the introduction of a wide vocabulary used to describe different aspects of these communities and their environments. In this chapter of the thesis, key terms, such as microbiota, microbiome, taxonomy, 16S ribosomal RNA and diversity will be defined.

Human microbiota

The human body, including mucosal and skin environments, is not only composed of somatic cells but also of a multitude of microbial cells derived from commensal, symbiotic and pathogenic bacteria, viruses, archaea and fungi (1). Together, these microorganisms form a complex bacterial ecosystem termed the human microbiota.

Gut microbiota

The human gut microbiota is the microbial ecosystem of the gastrointestinal digestive tract and is among the most complex of the body sites, including 500 to 1,000 different species (2,3). In most scientific publications, the gut microbiota refers to the bacterial population present in the digestive tract, without taking into account other microorganisms (i.e. viruses, archaea and fungi).

Gut microbiome

These trillions of microorganisms interact with their host through the expression of several millions of genes, which together comprise the human microbiome (4). Each bacterial strain has a genome containing thousands of genes, offering more genetic diversity than the human genome (2). A rough approximation of 1,000 bacterial species in the gut with 2,000 genes per species yields an estimate of 2,000,000 genes, 100 times the number of approximately 20,000 genes composing the human genome (5,6).

In many studies, the terms “microbiome” and “microbiota” are used interchangeably and are often synonymous. Even if these definitions are overlapping, small but relevant differences exist (7) (Table 1).

Table 1. Differences between three major terms of the vocabulary of microbiome research

| Microbiome | Microbiota | Metagenome |
|--|---|--|
| The microorganisms, their genomes and the surrounding environmental conditions | The microorganisms present in a defined environment | The collection of genomes and genes from the members of a microbiota |
| Refers to the bacteria (primary) and their genes (secondary) | Refers to the taxonomy of microorganisms | Refers to the collective functions of microbial genes |

Bacterial taxonomy

Bacterial taxonomy is the rank-based classification of bacteria. A taxon groups together different organisms to form a unit. The current bacterial classification includes domain, phyla, class, order, family, genus and species. The species constitutes the basic unit in the classification of living organisms (8). Nowadays, the most generally applied method for determining phylogenetic relationships between microorganisms is based on metagenomics, as high-throughput sequencing technologies have seen a rapid development in recent years. The purpose of metagenomics is to quantify the DNA of a multitude of species in a particular ecosystem at once, allowing the identification of non-cultivable bacterial species by standard methods in laboratories (9,10). Two sequencing approaches are used today: targeted metagenomics, consisting in amplifying and sequencing a single gene present in several species (11), and shotgun metagenomics, consisting in sequencing all the DNA from all organisms in a sample (12). Comparative analysis of the 16S ribosomal RNA (or 16S rRNA) gene sequences is particularly common for the study of the gut microbiome (13).

16S ribosomal RNA

16S rRNA is part of the 30S small subunit of the ribosome present in every prokaryotic cell. The gene encoding for the subunit, 16S rRNA gene, and its sequence is approximately 1,550 base pairs long (14). The 16S rRNA gene is used as a

phylogenetic marker as it is highly conserved between different species of bacteria and archaea (15). In addition to highly conserved primer binding sites, 16S rRNA gene sequences contain hypervariable regions that can provide species-specific signature sequences useful for identification of bacteria (16) (Figure 1).

Figure 1. Schematic representation of ribosome complex and 16S rRNA gene

From Fukuda et al, 2016 (17)

Different DNA-based techniques, such as quantitative PCR (qPCR) or 16S rRNA sequencing, are widely used in microbiology studies to identify diversity in bacteria. When analysing 16S rRNA using qPCR, a universal primer is applied to the sample. The partial 16S gene amplicons that result from this primer contain the hypervariable regions, which is compared to other known sequences through sequence alignment. The result helps deduce phylogenetic relationships between bacteria. qPCR is a quantitative technique with the advantage of being fast, specific and precise for the detection of minor populations of bacteria (18). However, the main disadvantage of qPCR is that the primers are designed to only quantify a selection of specific bacterial strains.

16S rRNA sequencing has been widely used for identification and taxonomic classification of bacterial species. 16s rRNA sequencing refers to sequencing amplicons of the 16s rRNA gene. While sequencing the entire 16s rRNA gene is difficult due to the read length restrictions of many next generation sequencing platforms, sequencing one or more hypervariable regions is relatively rapid and cheap

(19). In contrast to qPCR, 16S rRNA sequencing does not only focus on specific bacterial strains but rather on the complex bacterial community. Using 16S rRNA gene sequences, numerous bacterial genera and species have been reclassified and renamed, classification of uncultivable bacteria has been made possible, phylogenetic relationships have been determined, and the discovery and classification of novel bacterial strains has been facilitated (20). However, although 16S rRNA gene sequencing is highly useful in regard to bacterial classification, it has low phylogenetic power at the species level and poor discriminatory power for some genera (21).

Operational taxonomic units (OTUs) are clusters of similar sequence variants of the 16S rRNA gene sequences (22). Each of these clusters are intended to represent a taxonomic unit of a bacteria species depending on the sequence similarity threshold. In past years, using a 97% identity cut-off was a standard approach to distinguish bacteria at the genus level. Recent approaches are now focused towards amplicon sequence variants (ASVs), focusing on minor differences (in many cases single nucleotide variations) to identify unique bacterial species (23,24).

Microbial diversity

Changes in the microbiome composition and population diversity, is typically measured with taxonomic diversity. The taxonomic diversity is defined by two components: the richness which describes how many different types of bacteria are observed in a sample, in terms of their taxonomic ranking and the evenness, which designates how evenly these bacteria are distributed (25).

To measure biodiversity, two concepts are generally used in microbiome studies: alpha and beta diversity (26). The alpha diversity refers to the diversity within a single sample and is usually expressed by the number of species in that ecosystem. The beta diversity shows the difference between microbial communities and generally focuses on taxonomic abundance profiles from different samples.

Even though there is no general agreement on which diversity index is the best to use, several diversity indices have been commonly used to study microbial diversity (Table 2). For alpha diversity, these metrics are the Shannon diversity index, inverse Simpson

index, and the number of observed OTUs/ASVs. For beta diversity, these metrics include Bray-Curtis dissimilarity, Jaccard index and UniFrac.

Table 2. Ecological diversity measures commonly used in microbiome studies

| Diversity indices | Description | References |
|----------------------------------|--|------------|
| Shannon diversity index | Based on species richness and species evenness: more weight on species richness | (27) |
| Inverse Simpson index | Based on species richness and species evenness: more weight on species evenness | (27,28) |
| Observed OTUs/ASVs | Based on species richness: number of species present in a community | (29,30) |
| Bray-Curtis dissimilarity | Based on abundance: differences in microbial abundances between two samples | (31) |
| Jaccard index | Based on presence or absence of species: differences in microbial composition between two samples | (32) |
| UniFrac | Based on sequence distances: fraction of branch length shared between two samples or unique to one or the other sample | (33) |

1.1.2. Composition of the human gut microbiota

Composition at high taxonomic levels shows the overall stability of the gut microbiota between individuals. In healthy individuals, intestinal microbiota are typically dominated, at the phyla level, by Gram-negative *Bacteroidetes* and Gram-positive *Firmicutes*, with a smaller abundance of *Actinobacteria* (34,35). However, the proportion of these phyla is not static, and different bacterial strains may compete to fulfil distinct ecological niches, inducing considerable inter-individual variation between phenotypically similar hosts. Therefore, each individual harbours radically different complexity and diversity of bacterial community in the digestive tract, making each gut microbiota unique (36,37).

Our understanding of what leads to inter-individual variation in diversity remains limited, even if several studies tend to show that a number of host (e.g. genetics, age) and lifestyle factors (e.g. diet, obesity, medications, mode of delivery at birth) could

influence the composition of the gut microbiota through the life-course, potentially to the benefit or detriment of the host (38–42) (Figure 2).

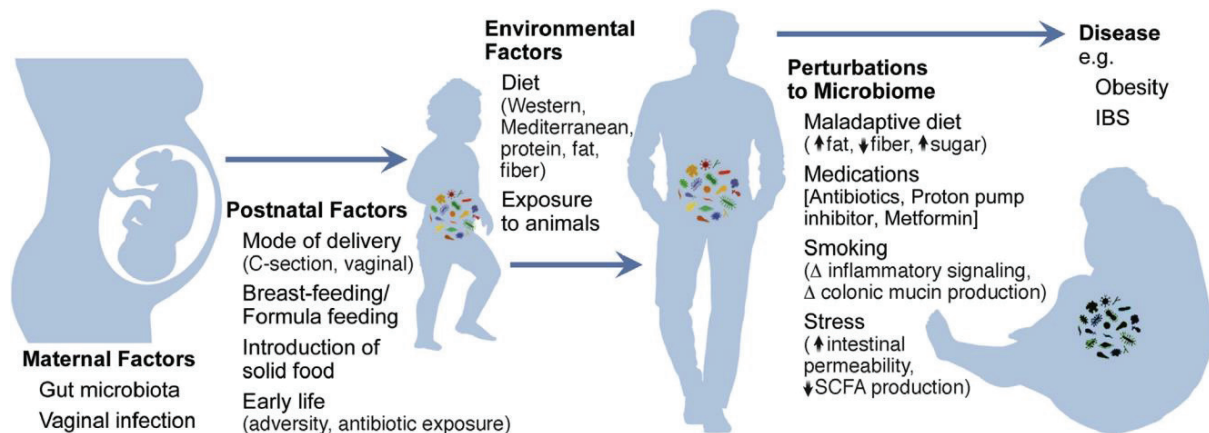

Figure 2. Evolution of the gut microbiome over the human life-course

Adapted from Dong & Gupta, 2019 (43), SCFA: short-chain fatty acid, IBS: inflammatory bowel syndrome

Typically-consumed diets, such as the Western diet and the Mediterranean diet, can have a significant impact on the gut microbiome (44). The Western diet, characterised by high-fat, high-sugar, high level of red and processed meat, high levels of refined grains and a lower level of fibre, was associated to a decrease in overall bacterial richness/diversity, and beneficial *Bifidobacteria* and *Eubacteria* (43,45). This alteration of the gut microbiome was associated with gut barrier degradation, reduced levels of short-chain fatty acids (SCFAs), higher levels of lipopolysaccharides (LPS) and inflammation (46,47). In comparison, the Mediterranean diet, characterised by a beneficial fatty acid profile, higher intake of fibre, vegetables, and fruits, and with lower intake of sugar and red meat, was associated to increased bacterial richness/diversity, higher levels of SCFAs and decreased inflammation (43,48). Consumption of dietary fibre increases bacterial richness and diversity with a relative abundance in such genera as *Prevotella* and *Treponema*, and enhance the production of SCFAs (39,49).

In addition to diet and other early life events (50), such as the mode of delivery at birth and breast-feeding, there are many other lifestyle exposures throughout adulthood that can lead to changes in microbial composition. Certain medications, such as antibiotics and proton pump inhibitors, can trigger gut microbiome imbalances which can persist

over time and increase the host's susceptibility to infection and metabolic syndrome (51,52). Smoking has also been associated to changes in gut microbiota composition, as shown by strong microbial alterations before and after smoking cessation (53). More recently, in addition to the previously mentioned factors that are relatively well described in the literature, it has been shown that alcohol consumption and bowel movement quality might have a very strong impact on the gut microbiome (54–56). Most importantly, in contrast to other dietary factors influencing the gut microbiome, these two factors have also been shown to differ when comparing diseased subjects to healthy individuals and to influence disease associations by confounding the effects of disease (56).

1.2. Gut microbiome metabolism

The gut microbiome is highly metabolically active and helps define essential physiological functions such as digestion of food and extraction of nutrients (57), drug metabolism (58), and modification of the host immune response and metabolism (59). Interestingly, microbial diversity between individuals does not appear to critically influence core functions in microbial metabolism, including the production of SCFAs via fermentation of complex polysaccharides, deconjugation of bile acids, synthesis of specific LPS and the biosynthesis of some essential amino acids and vitamins (5,60–62).

1.2.1. Short-chain fatty acids

Since the human body lacks the digestive enzymes required to digest many dietary plant polysaccharides and oligosaccharides, these dietary fibres are metabolically processed by the gut microbiota (63,64). Bacterial fermentation of dietary non-digestible polysaccharides in the human colon produces SCFAs, largely composed of acetate, propionate and butyrate (65,66). These end products of bacterial fermentation are produced by different bacteria in the colon. For instance, butyrate is produced by several bacteria from the phyla *Firmicutes* such as *Faecalibacterium prausnitzii*, or *Roseburia spp* (67).

SCFAs play a major role in the maintenance of normal physiology in the host including the stimulation of water absorption, the production of energy for intestinal epithelial cell

growth, and can either be absorbed from the colon or bind to free fatty acid receptors which are expressed in the intestinal epithelium (68–70). More specifically, butyrate is an important source of energy for colonic epithelial cells, propionate is utilized in the liver as a substrate for the production of glucose via gluconeogenesis, and acetate, once transformed into acetyl-CoA, is an important biochemical intermediate in human metabolism (68,71).

1.2.2. Bile acids

Bile acids represent the primary pathway for cholesterol catabolism in the liver and they primarily promote absorption of lipids, including fat-soluble vitamins in the intestine (72). Deconjugation of primary bile acids by the gut microbiota results in the formation of secondary bile acids, including deoxycholic and lithocholic acids, derived from cholic acid and chenodeoxycholic acid, respectively (73).

These bioconversions modulate the signalling properties of bile acids through the nuclear farnesoid X receptor and the G protein-coupled membrane receptor 5, which regulate diverse metabolic pathways in relation to glucose and lipid metabolism in the host (74). More precisely, secondary bile acids regulate the hepatic triglyceride pool via nuclear farnesoid X receptor-dependent inhibition of sterol regulatory element binding protein-1, therefore inhibiting lipogenesis (75). Secondary bile acids also stimulate the secretion of the incretin glucagon like peptide-1 through binding to the G protein-coupled membrane receptor 5 on enteroendocrine cells, thus improving insulin sensitivity, attenuating weight gain and increasing energy expenses (76).

1.2.3. Lipopolysaccharide

LPS is the major component of the outer layer of the membrane of Gram-negative bacteria and is, in non-capsulated strains, exposed on the cell surface (77). Distinct structures of LPS can be found on the surface of many pathogenic bacteria (e.g. *Escherichia coli*, *Salmonella*, *Yersinia pestis*) and therefore, have been termed endotoxin in reference to the cell-associated toxicity. LPS performs several functions in Gram-negative bacteria such as serving as a major structural component of the outer membrane, transforming the outer membrane into an effective permeability barrier against small, hydrophobic molecules and most importantly (78), playing a crucial role

in bacteria-host interactions by modulating responses by the host immune system. Gut microbial LPS is thought to be one of the most important mediators of the microbiome's influence on host physiology, notably because chronic immune cell activation is, in part, caused by the LPS-mediated stimulation of toll-like receptor 4 (79). However, our understanding of the mechanisms that support host-microbe interactions through LPS is still limited. While many assume that proinflammatory signalling by LPS is a central feature of the gut microbiome activity, others consider that proinflammatory pathways commonly triggered by bacterial pathogens upon interaction with the host are, in fact, actively repressed by beneficial bacteria of the gut microbiome to maintain homeostasis in the gut (80,81).

1.2.4. Amino acids

The gut microbiota is also involved in the digestion and metabolism of endogenous and exogenously-derived amino acids. Amino acids are among the major nutrients in the diet and regulate energy and protein homeostasis in organisms (82,83). Some functional amino acids, such as tryptophan, glutamine, methionine, and branched-chain amino acids, also have beneficial effects on the immune system through modulation of key metabolic signalling pathways (84). Along the gastrointestinal tract, alimentary and endogenous proteins are hydrolysed into peptides and amino acids by host- and bacteria-derived proteases and peptidases (85). A number of microorganisms, such as bacteria belonging to *Clostridium* and *Streptococcus*, are particularly involved in amino acid fermentation in the large intestine (86).

Amino acid-fermenting bacteria are not only important for protein digestion and subsequent amino acid absorption, but they also secrete various metabolites, characterised by nitrogen- and sulfur-containing material. The products are, sometimes, detrimental to the health of the host (87) but may also influence cellular signalling pathways and exert immune and barrier effects and thus, maintain homeostasis of the host (83). After being metabolised by microorganisms, amino acids can also be used to synthesise constituents, such as SCFAs or other bacterial proteins (88). Additionally, the gut bacteria can be involved in *de novo* biosynthesis of certain amino acids, suggesting that the exchange of amino acids between the host and the gut microbiota is bidirectional (89).

1.3. Gut microbiome in insulin resistance, diabetes and cancer

Elaborate mechanisms relying on host-driven tolerance are required to maintain the host-microbe symbiosis in the intestine, including physical barriers of the oriented gut tissues or secretion of antimicrobial peptides and secreted antibodies (90). However, this symbiosis is based on a dynamic and fragile equilibrium, and disturbances of the interactions between the host and the gut microbiome have been associated with several chronic diseases such as obesity (91,92), diabetes (93,94) and potentially different types of cancer (95,96).

1.3.1. Gut microbiome in insulin resistance and metabolic syndrome

Type 2 diabetes (T2D) has reached global epidemic proportions and is recognised as a major cause of morbidity and mortality (97). Insulin resistance, characterised as the reduced sensitivity of glucose storage tissues to insulin-mediated biologic activity, is a condition that precedes the development of T2D (98), and often accompanies obesity, though not exclusively. Indeed, individuals with insulin resistance are not systematically overweight or obese (99) and the existence of metabolically-healthy obese and metabolically unhealthy normal-weight individuals has been described in previous studies (100). Insulin resistance is also related to poor glucose control and high levels of chronic inflammation, which together, comprise elements of the metabolic syndrome (101). The incidence of metabolic syndrome often parallels the incidence of obesity and incidence of T2D, and it has been estimated that more than 20% of adults worldwide are known to have metabolic syndrome (102). However, the prevalence of metabolic syndrome varies depending on environmental factors, the age and gender composition of the population, genetic differences, and lifestyle factors including physical activity level and eating habits (103,104). Despite the well-established epidemiological associations between metabolic syndrome and its related metabolic parameters (e.g. insulin resistance) and chronic diseases, the biological mechanisms underlying its development remain to be deciphered.

Insulin and insulin-like growth factor-1 mediate their biological effects via the insulin and insulin-like growth factor-1 receptors. Cellular actions of insulin and insulin-like growth factor-1 involve a wide variety of effects on post-receptor signalling pathways

within target cells (105). These signalling pathways contain several points of regulation, signal divergence, and cross talk with other signalling cascades that are essential to mediate the variety of insulin and insulin-like growth factor-1 biological responses (106). Mechanisms of insulin resistance are therefore multifactorial. In most cases, insulin resistance is caused by cellular perturbations, such as lipotoxicity, inflammation, glucotoxicity, mitochondrial dysfunction, and endoplasmic reticulum stress (105). These potential complex mechanisms lead to deregulation of genes and inhibitory protein modifications and result in impaired insulin and insulin-like growth factor-1 action (Table 3).

Previous studies have suggested that the gut microbiome might influence host metabolic health through several pathways that are directly or indirectly related to insulin resistance development (93,94,107,108). These pathways included energy extraction, intestinal barrier integrity, metabolism of bile acids and host metabolic and signalling pathways (109). Alterations of microbial composition and functionality in T2D patients compared to healthy participants have been described (93,94,110). For example, circulating levels of branched-chain amino acids have been positively associated with insulin resistance (111) and correlate with specific changes in gut microbiome composition (e.g. *P. copri* and *B. vulgatus*) and functions of individuals with insulin resistance (112). In addition, low bacterial diversity, characterised by the reduction in butyrate-producing bacteria (e.g. *Roseburia* and *Faecalibacterium prausnitzii*) and the increase in mucin-degrading bacteria, was associated with impaired gut integrity causing low-grade inflammation of visceral adipose tissue through endotoxemia (107,113,114) and may provide a link between obesity and insulin resistance (115). If animal and human studies have identified relevant differences in intestinal microbiota composition in subjects with insulin resistance related chronic diseases, the magnitude of effect of the gut microbiome on metabolic functions remains to be proven (116).

Table 3. Possible molecular mechanisms of insulin resistance pathogenesis

From Boucher et al, 2014 (105)

| Cause | Mechanism | Effect |
|---|---|---|
| Lipotoxicity Inflammation Hyperglycemia Mitochondrial dysfunction Endoplasmic reticulum stress | Activation of Ser/Thr kinases | Inhibitory phosphorylation of insulin-signalling molecules |
| Genetic mutations | Point mutations in insulin receptor and insulin-signalling molecules | Increased protein turnover Reduced expression and ligand affinity Decreased signalling capacities |
| | Single-nucleotide polymorphism causing increased gene expression | Increased phosphatase and tensin homolog action leading to reduced phosphatidylinositol (3,4,5)-triphosphate levels |
| Lipotoxicity | Hyperactivation of protein phosphatase protein phosphatase 2A | Reduced phosphorylation of insulin receptor and insulin-signalling molecules |
| Inflammation | Cytokine-induced suppressor of cytokine signalling-3 protein activation | Inhibition of insulin receptor tyrosine kinase activity Competition for insulin receptor substrate binding to insulin receptor Increased insulin receptor substrate degradation |
| | Cytokine-induced reduction in gene expression | Decreased expression of insulin-signalling molecules |
| Hyperglycaemia | Glycation of insulin-signalling molecules | Reduced affinity for insulin receptor Decreased DNA-binding capacities of transcription factors |
| | Hyperactivation of protein phosphatase protein phosphatase 2A | Reduced phosphorylation of insulin receptor and insulin-signalling molecules |
| Hyperinsulinemia | Hyperactivation of leucine-rich repeat protein phosphatases-1 and Grb14 | Decreased Akt Ser 473 phosphorylation Competition for insulin receptor substrate binding to insulin receptor |

Insulin resistance and subsequent hyperinsulinemia and T2D are conditions which are associated with increased risk of cancer at a number of anatomical sites (117). For example, metabolic changes such as hyperinsulinemia and insulin resistance are associated with colorectal cancer (118–120). The mechanisms linking insulin resistance and metabolic dysfunction with colorectal cancer are not fully understood but may reflect enhanced signalling through insulin receptors and insulin-like growth factors (i.e. insulin-like growth factor-1 and 2) and signal transduction to pro-mitogenic and anti-apoptotic pathways that enable cell proliferation and survival of transformed cells (121). Insulin stimulates cell proliferation by binding with low affinity to the insulin-like growth factor-1 receptor, inducing high serum levels of insulin-like growth factor-1 and increasing risk of cancer, including colorectal cancer (122,123). Furthermore, some cancer cells promote tumor proliferation by locally producing insulin-like growth factor-2 which binds with high affinity to foetal isoforms of the insulin receptor in tumor cells (124). Since insulin resistance, T2D and obesity are known cancer-promoting conditions, understanding the relationship between the gut microbiome and metabolic syndrome might help to understand the mechanisms of cancer development and open new possibilities for preventive strategies as well as screening, diagnosis, and treatment (125).

1.3.2. Role of the gut microbiome in cancer

There is growing evidence that the gut microbiota potentially influence the initiation and progression of tumor development (126,127). Since disturbances of the host-microbiome homeostasis have been associated with many established hallmarks of cancer (128), the gut microbiome likely influences cancer risk at different levels, including cancer initiation, promotion, dissemination, and response to therapy (129). Broadly, these hallmarks comprise dysregulations of host metabolism (93,107,108) and immune function (59,79), perturbations of homeostatic processes promoting chronic inflammation (130–132) and promotion of genome instability and mutations (133,134) (Figure 3).

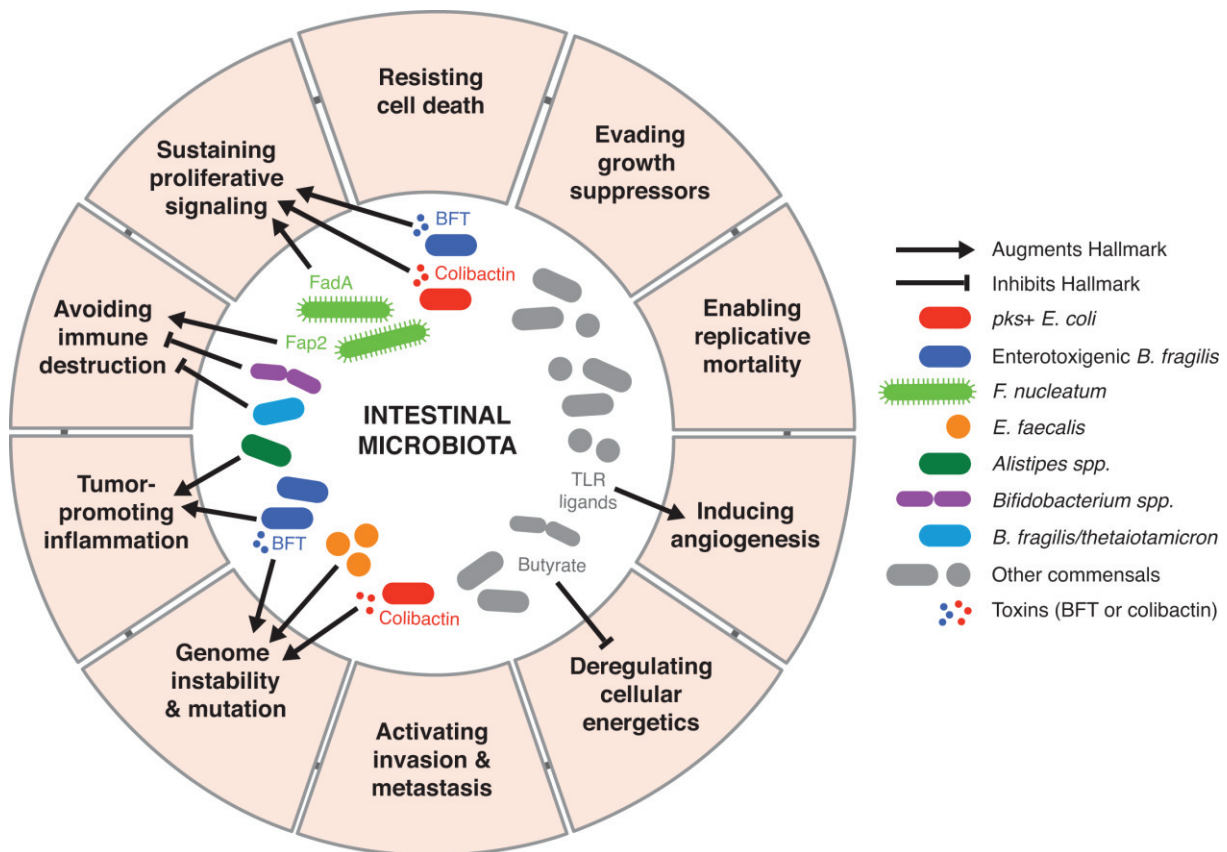

Figure 3. The gut microbiome influences several hallmarks of cancer through diverse pathways

From Fulbright et al, 2017 (128)

2. Colorectal cancer

Although recent studies have implicated the gut microbiota in the development of cancers at distal sites (135,136), the earliest observations linking the microbiota with the hallmarks of cancer have primarily focused on colorectal cancer as the most complex and dense populations of endogenous microorganisms are found within the gastrointestinal tract.

2.1. Colorectal cancer: pathophysiology, epidemiology and etiology

2.1.1. Pathophysiology

Colorectal cancer develops through four main stages: initiation, promotion progression and metastasis (137). Briefly, initiation involves irreversible genetic damage to target cells that allow neoplastic transformations occur. The initiated cells proliferate during the promotion stage, inducing abnormal growth. During the progression phase, through

the gradual accumulation of genetic and epigenetic alterations, benign tumour cells transform into malignant cancer cells and acquire aggressive characteristics and metastatic potential. Finally, metastasis is marked by the spread of cancer cells from the primary organ to other organs or tissues through the bloodstream or the lymphatic system. The duration of each phase is difficult to estimate but these mechanisms generally take a long time and decades may be required for all stages to be completed in colorectal cancer (138).

Colorectal cancer occurs through at least three distinct carcinogenic pathways (139). The adenoma-carcinoma sequence pathway accounts for 85 to 90% of sporadic colorectal cancer. Normal cells progress to small adenoma, to large adenoma and, finally, to cancer. This pathway is predominantly associated with chromosomal instability (140). In addition, the serrated pathway accounts for 10 to 15% of sporadic colorectal cancer. This model is characterised by the progression from normal cells, to hyperplastic polyp, to sessile serrated adenomas and, finally, to cancer (141). This pathway is predominantly associated with CpG island methylator phenotype (142). Finally, a twofold increased risk of colorectal cancer was previously observed in patients with inflammatory bowel disease (143). Due to the low incidence of inflammatory bowel disease, the inflammatory pathway explains less than 2% of all colorectal cancers. Driven by chronic inflammation, normal cells progress to indefinite dysplasia, to low-grade dysplasia, to high-grade dysplasia and, finally, to cancer (144).

2.1.2. Epidemiology

Worldwide, colorectal cancer is the third most common cancer in men and the second most common cancer in women, and is also the second leading cause of cancer-related death in the world among both sexes combined (145). Over the next 15 years, the number of cases of colorectal cancer is expected to increase by 72% to more than 3 million (146). While the incidence of colorectal cancer in many countries with a high human development index has decreased among those older than 50 years, a recent study established that rates of colorectal cancer in individuals younger than 50 years increased by up to 4% per year (147). In addition, in many countries that underwent major development transitions, particularly in Eastern Europe, Asia and South America, increases in both colorectal cancer incidence and mortality have been

observed (146,148). The rise in incidence in countries in transition and the generational changes may reflect the role of secular changes in colorectal cancer risk factors that have influenced incidence rates.

2.1.3. Etiology

Although genetic factors, including family history of colorectal cancer and hereditary cancer syndromes (143,149), as well as chronic inflammation induced by inflammatory bowel diseases, contribute to colorectal cancer development, there is strong evidence that many modifiable dietary and lifestyle factors affect colorectal cancer risk (Table 4) (150,151). These factors include obesity, low physical activity and sedentary lifestyle, poor diets (such as higher consumption of red and processed meat, high fat, low fibre, low whole grain and low calcium), smoking tobacco and excessive alcohol consumption (152–154).

Table 4. Dietary and lifestyle factors associated with strong evidence to colorectal cancer risk

Adapted from World Cancer Research Fund, 2017 (152)

| | Decreases risk | Increases risk |
|-------------------|--|---|
| Convincing | Physical activity | Processed meat Alcoholic drinks Body fatness Adult attained height |
| Probable | Wholegrains Foods containing dietary fibre Dairy products Calcium supplements | Red meat |

Further, two dietary patterns have been consistently observed to be associated with colorectal cancer. The first pattern indicates a potential protective effect of a diet characterised by high intake of fruit and vegetables as well as fibre and whole grains, nuts or legumes, fish or other seafood, calcium and dairy products (152). The other pattern, considered as unhealthy and mainly represented by the so-called Western diet, is characterised by high intake of red and processed meat, sugar-sweetened beverages, refined grains, desserts and potatoes (155). Biological mechanisms linking dietary patterns and colorectal cancer are probably multifaceted, reflecting a complex

interplay of various dietary components instead of the effect of individual nutrients or specific foods (155).

Physical activity might also reduce colorectal cancer risk through its beneficial effects on gut motility, the immune system, inflammation and metabolic hormones (156). In addition, regardless of the level of physical activity, a sedentary lifestyle, as characterised by prolonged sitting, is emerging as a risk factor for colorectal cancer by impairing skeletal muscle function, which facilitates insulin resistance and promotes colorectal carcinogenesis (157,158).

As previously indicated, overweight, obesity and T2D are established risk factors for colorectal cancer and may directly account for more than 10% of colorectal cancer cases worldwide (159,160). In obesity there is dysregulation of adipose tissue metabolism and immunology characterised by high levels of proinflammatory adipokines, which could contribute to the development of chronic low-grade inflammation promoting tumour growth and progression (161,162). However, important questions remain regarding the mechanisms underlying the link between obesity and colorectal cancer. For example, it is not known if obesity-related inflammation increases colorectal cancer risk directly or secondarily through processes such as insulin resistance (163).

2.2. Gut microbiome and colorectal cancer

Advances in characterising the gut microbiome have offered potential insights into the etiology of colorectal cancer. In fecal samples collected within a case-control study, colorectal cancer risk was positively associated with decreased bacterial diversity with enrichment of *Bacteroidetes* and depletion of *Firmicutes* in colorectal cancer cases compared to non-cancer controls (95). In another case-control study, the composition of the gut microbiota was investigated in colorectal cancer precursors and revealed differences in the relative distribution of eight phyla between adenomatous and control colorectal tissues (164). Accumulating evidence supports the likelihood that the collective activity of the gut microbiota might influence colorectal cancer development and progression (165,166). However, over the past decade, several species have garnered specific interest for the potential roles in colorectal carcinogenesis.

Data from *in vitro* and murine models have demonstrated that *Fusobacterium nucleatum* might promote colorectal cancer cell proliferation and increase tumor growth rates (167). Several mechanisms have been proposed to explain these findings (Figure 4). *F. nucleatum* promotes cell proliferation by binding to E-cadherin on the colorectal cancer cell surface through FadA adhesin and activates the oncogenic Wnt/ β -catenin signalling pathway (168). Through the effect of Fap2 adhesin, *F. nucleatum* facilitates colorectal cancer enrichment by binding to a disaccharide sugar motif and alters the function of tumor-infiltrating lymphocytes and natural killer cells by binding to the inhibitory immune receptor TIGIT (169,170). *F. nucleatum* also facilitates resistance to chemotherapy by activating autophagy through LPS and Toll-like receptor 4 expressed on colorectal cancer cells (171).

Figure 4. Three examples of microorganisms that might drive colorectal cancer

From Garrett, 2015 (129)

In addition, in mice, enterotoxigenic *Bacteroides fragilis*, a pathogen that causes diarrhoea and inflammation, potentiates colorectal carcinogenesis and was detected in biofilms covering human adenocarcinomas and adenomas (172). The importance of colibactin-producing *Escherichia coli* in colorectal cancer tumorigenesis has been confirmed, when the *E. coli* genotoxin-producing strains (known to induce double-strand DNA breaks and cell cycle arrest) were found in more than 50% of colorectal cancer cases (173).

For all the aforementioned examples, it is apparent that variation in the gut microbiota and potential link with colorectal neoplasia might represent a promising hypothesis that could offer insights to unexplained features of the epidemiology of colorectal cancer. However, it remains unclear whether bacterial features of the gut microbiota have a causative role in colorectal carcinogenesis and due to several limitations, evidence on the potential mechanisms involved are still too weak to draw definitive conclusions.

2.3. Colorectal cancer screening and gut microbiome

As described above, colorectal cancers typically develop from normal epithelium through sequential phases of adenomatous dysplasia over a period that can span decades. Colorectal cancer survival was therefore strongly correlated with stage at diagnosis, which supports the importance of colorectal cancer screening programs where neoplastic lesions can be detected at an early stage (174). The recommended screening for the average-risk population (i.e. individuals aged 50 years or older, with no additional risk factors) is one of the following: an annual or biennial stool test, sigmoidoscopy every 5 years, or colonoscopy every 10 years (Figure 5) (175).

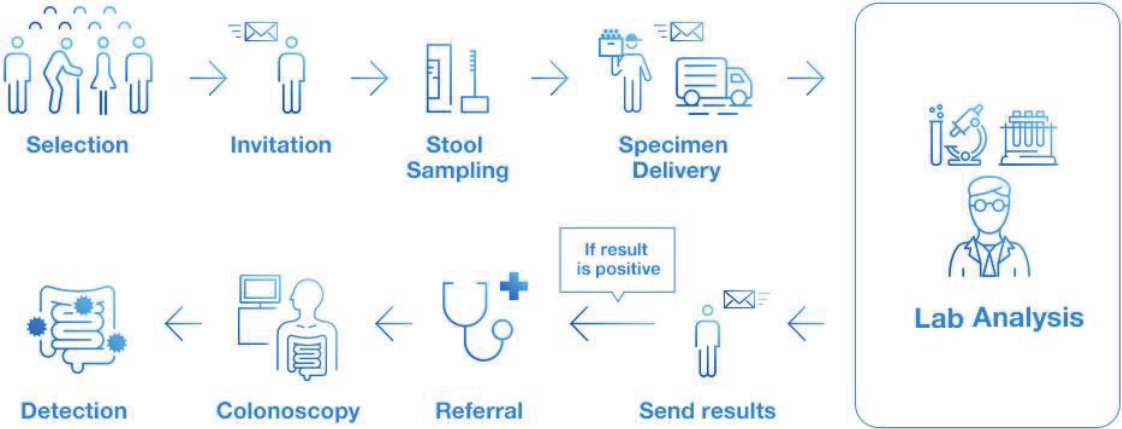

Figure 5. Schematic representation of colorectal cancer screening protocol using FIT

From Eiken Chemical Co., Ltd. (176)

Several stool tests are being used in countries where colorectal cancer screening registries are implemented, each of these modalities differing by specificity, sensitivity, acceptance, and economic impact. One screening tool, which has been widely implemented for its excellent specificity, is the fecal occult blood test (FOBT). Despite

its poor sensitivity for the detection of colorectal adenomas, significant reductions in colorectal cancer mortality have been reported with the use of FOBT in screening-based randomised trials (174,177,178). Subsequently developed after FOBT, the fecal immunochemical test (FIT) for the detection of human haemoglobin in stool has higher sensitivity for the detection of colorectal cancers and early stages compared with FOBT (179,180). Observational studies on the evaluation of FIT in colorectal cancer screening programs are very consistent and one, reported relative risks of death from colorectal cancer 10% to 40% lower among individuals screened by FIT (181–183). Therefore, the FIT has been recommended as the first option for detecting fecal occult blood in colorectal cancer screening (184) and is increasingly being used in countries with an organised colorectal cancer screening program (185). For example, in France, the FIT has been offered every two years to average-risk individuals, aged 50 to 74, since 2015. According to Santé Publique France, approximately 5,300,000 individuals were screened by FIT between 2018 and 2019, in France. Of these, around 198,000 (3.8%) were FIT-positives (186). These colorectal cancer screening registries in which millions of FOBT or FIT samples are being collected each year might provide rich opportunities to establish cohorts of individuals with pre-diagnostic collected fecal samples.

Indeed, epidemiological studies of the association between the gut microbiome and colorectal cancer development have so far been very limited, usually with small sample sizes and case-control and other cross-sectional designs without repeated measurements. Thus, due to potential reverse causality, caution is required in the interpretation of colorectal cancer-microbiome associations (187). In data based on case–control studies, it is not possible to determine whether the carcinogenic process changes the local environment and creates a new niche for microorganisms or whether alterations in the microbial population contribute to carcinogenesis. Repeated, prospectively collected samples from population-based cohort studies are necessary for better understanding of the temporal nature of microbial associations with colorectal cancer.

3. Thesis aim and objectives

The main aim of this thesis was to contribute to unravelling the putative associations of the gut microbiome with colorectal cancer development by strengthening epidemiologic evidence on the relationship between the gut microbiome and established colorectal cancer risk factors, including insulin resistance and chronic inflammation, and by evaluating fecal sample collection methods used in ongoing screening programs with a view to providing the necessary evidence for establishing future cohorts with prediagnostic fecal samples. To address this over-arching aim, this thesis has been divided into three objectives.

3.1. The human microbiome in relation to cancer risk

The first part of the thesis aimed to summarize the current epidemiological literature that has been published in the past decade on the association of the microbiome with cancer. Indeed, while some reviews and meta-analyses focusing on microbiome profiles for single cancer sites have already been published, no systematic overview of the most significant associations between microbiome composition (e.g. taxa and diversity) and different cancer sites was published to date. Due to the diversity of published data, an overview of available epidemiologic evidence linking the microbiome with cancer was needed.

Objective I:

Evaluate the strengths and weaknesses of the current evidence on the relationship between the human microbiome and cancer in epidemiologic studies.

3.2. Markers of metabolic health and gut microbiome diversity

The second part of the thesis aimed to investigate the association between insulin resistance and inflammation, recognised colorectal cancer risk factors, and the gut microbiome in population-based epidemiological studies. While the gut microbiome has been hypothesised to influence insulin resistance development, human data on insulin resistance and other metabolic parameters and the gut microbiome are still limited as very few cohorts have collected both blood and fecal specimens. Insulin resistance lies on the causal pathways of diabetes and other metabolic diseases, and

is an established risk factor for colorectal cancer. Therefore, deciphering the pathophysiology of insulin resistance and inflammation using population-based data might help to understand the mechanisms of colorectal cancer development and strengthen evidence for potential preventive strategies.

Objective II:

Investigate the association of gut bacteria 16S rRNA gene sequence data with serologic levels of homeostatic model for insulin resistance, glycated haemoglobin and C-reactive protein in two distinct population-based cohorts, the Northern Finland Birth Cohort 1966 and TwinsUK.

3.3. Comparison of fecal sample collection methods for microbial analysis

The third part of the thesis evaluated microbiome stability and accuracy in fecal samples collected using different methods employed in ongoing colorectal cancer screening programs. Indeed, to potentially inform the establishment of international studies with repeated, prospectively collected fecal specimens based in colorectal cancer screening programs, methodologic work was needed to test FIT and specimen collection cards used in countries where different screening devices are employed.

Objective III:

Compare the impact of different fecal collection methods currently used in ongoing colorectal cancer screening programs on microbiome technical reproducibility, accuracy and stability.

Chapter II: The human microbiome in relation to cancer risk: a systematic review of epidemiological studies

1. Background

The gut microbiome has potentially been associated with cancer development (128) but due to the diversity of published data, the exact mechanisms of this relationship are not clear (187). A large number of individual observational studies that have examined the association of the microbiome with single cancer types have been published in the past decade, however, no systematic overview of the most significant associations between microbiome composition and diversity, and different cancer sites was published to date.

2. Objective

The objective of this study was to evaluate the strengths and weaknesses of the current evidence on the relationship between the human microbiome and cancer in epidemiologic studies.

3. Methods

Inclusion and exclusion criteria

A systematic review was conducted to identify peer-reviewed publications related to the human microbiome and cancer. Observational studies (i.e. case–control, including case-crossover design or cohort studies) and randomized controlled trials were considered for inclusion. Reviews, case reports, and other studies without a comparison group, as well as *in vitro* and animal studies were excluded. Adult humans with or without any type of cancer were included while underage persons (<18 years) were excluded. Studies investigating the prevalence or incidence of cancer and its association with the human microbiome were considered for inclusion. Studies investigating only precancerous lesions/conditions (no malignant conditions) were excluded. Studies focusing on single bacteria instead of communities of microorganisms were excluded.

Data collection and analysis

Tailored search strings (see Supplementary Material Table S1 in annex) were used to search for relevant articles from database conception until December 2019 via the PubMed and EMBASE databases. Studies were reviewed and selected independently by four reviewers. Significant differences in relative abundance of taxa and/or diversity measures between cancer cases and controls were extracted and reported. If multiple analyses were run with different levels of adjustment, then the one with maximal adjustment for confounders was chosen. The methodologic quality of the included articles was assessed independently by two reviewers using the Newcastle-Ottawa quality assessment scale (188). An association was considered as “strong” when three or more publications reported a statistically significant association in the same direction and none were in the opposite direction. The association was deemed “suggestive” when two publications reported a statistically significant association in the same direction and none in the opposite direction.

4. Results

A total of 124 articles (including 15,764 subjects in total; 7,652 cancer cases vs. 8,112 controls) were included and used for this review. Among all the anatomical sites evaluated, the gut microbiome followed by the oral microbiome were most frequently studied. The majority of articles reported specific differences in microbiome diversity and/or composition between cases and control groups (including not only non-cancer patients but sometimes tissues). Fifty studies reported differences in gut microbiome composition between colorectal cancer patients and various controls. Overall, consistent findings showed that abundance of pro-inflammatory opportunistic taxa, such as *Fusobacterium*, *Parvimonas* and *Porphyromonas*, was increased in colorectal cancer patients while a depletion of butyrate-producing bacteria was observed. Sixteen studies described differences in oral microbiome composition between oral cancer patients and controls. Enrichment of *Fusobacterium* and depletion of *Streptococcus* were reported in patients with oral cancer compared with controls. The quality assessment demonstrated rather low quality for the “ascertainment of the exposure of interest” because studies often used different methods of ascertainment for cases and controls, for example, resection for cases while biopsy for controls. The large diversity

of parameters used to describe the microbial composition made it impossible to harmonize the different studies in a way that would allow meta-analysis.

5. Conclusion

Although strong evidence was available for certain taxa of the gut microbiome and colorectal cancer risk, and for the oral microbiome and oral cancer risk, for most of the microbiome taxa/indicators the evidence was still too weak to draw firm conclusions in relation to their role in cancer. Most findings now require validation in population-based prospective studies in which standardised methods are applied.

The Human Microbiome in Relation to Cancer Risk: A Systematic Review of Epidemiologic Studies

Inge Huybrechts¹, Semi Zouiuich¹, Astrid Loobuyck², Zeger Vandenbulcke², Emily Vogtmann³, Silvia Pisanu^{1,4}, Isabel Iguacel^{1,5}, Augustin Scalbert¹, Iciar Indave¹, Vitaly Smelov^{1,6}, Marc J. Gunter¹, and Nathalie Michels²

ABSTRACT

The microbiome has been hypothesized to play a role in cancer development. Because of the diversity of published data, an overview of available epidemiologic evidence linking the microbiome with cancer is now needed. We conducted a systematic review using a tailored search strategy in Medline and EMBASE databases to identify and summarize the current epidemiologic literature on the relationship between the microbiome and different cancer outcomes published until December 2019. We identified 124 eligible articles. The large diversity of parameters used to describe microbial composition made it impossible to harmonize the different studies in a way that would allow meta-analysis, therefore only a qualitative description of results could

be performed. Fifty studies reported differences in the gut microbiome between patients with colorectal cancer and various control groups. The most consistent findings were for *Fusobacterium*, *Porphyromonas*, and *Peptostreptococcus* being significantly enriched in fecal and mucosal samples from patients with colorectal cancer. For the oral microbiome, significantly increased and decreased abundance was reported for *Fusobacterium* and *Streptococcus*, respectively, in patients with oral cancer compared with controls. Overall, although there was a large amount of evidence for some of these alterations, most require validation in high-quality, preferably prospective, epidemiologic studies.

Introduction

The human microbiome defines either the microorganisms (bacteria, archaea, lower and higher eukaryotes, and viruses) found in and on the human body or their collective genomes (i.e., genetic material; refs. 1–3). Since the development of high-throughput approaches using next-generation sequencing, our understanding of the human microbiome, even the noncultivable microorganisms, has increased enormously, shedding light on its complexity (1, 4, 5). Although the gut microbiome has been most extensively studied, microorganisms also inhabit all of the barrier surfaces of the human body including the skin, the oral cavity, the nasopharynx, the esophagus and stomach, and also the vagina, the urinary tract, the lungs and others (4, 6). The composition of the microbiome varies depending on the anatomic site and it also differs between individuals (4). The microbiota, the ensemble of microorganisms living in a specific environment, form

a dynamic entity, and can change within an individual in response to diet and other external factors such as medication, environment, and lifestyle (1, 7, 8).

In addition to the role that microbial imbalance (9) may play in infectious and autoimmune conditions; there is a growing appreciation of potential influences on cancer development (3, 6). For example, the microbiota and its metabolic products influence the development and maintenance of inflammation, which has been broadly recognized to be one of the hallmarks of cancer (10–12). Inflammation has been demonstrated to promote cancer by promoting genetic instability and, once the tumor has been established, through the creation of a tumor-promoting microenvironment. In addition, the microbiota may also influence the development of cancer-promoting conditions, such as adiposity and insulin resistance (13–15). Because of these effects on host metabolism, cellular proliferation, inflammation, and immunity, the microbiome may influence cancer risk at different levels, including cancer initiation, promotion, dissemination, and response to therapy (6, 16). The effects of the microbiota on cancer risk can be local, situated at the interface where the organism interacts with the host tissue in which the cancer originates, or systemic, via the physiologic communication of the host organism and the microbiota through intact membranes or following alteration of barrier permeability in pathologic situations. This potential link between the microbiome and cancer development might offer new opportunities for cancer prevention by understanding etiologic pathways for screening, diagnosis, and treatment (2, 3, 17).

A large number of individual studies on the association of the microbiome with cancer have been published in the past decade, and an in-depth review of the literature is now needed. While some published reviews and meta-analyses focusing on microbiome profiles for single cancer sites were recently published (18–20), no systematic overview of the most significant associations between microbiome composition (e.g., taxa and diversity) and different cancer sites has been published to date. Therefore, the objective of this systematic review was not only to summarize the published data, but also to evaluate the strengths and weaknesses of the current evidence on the

relationship between the human microbiome and cancer in epidemiologic studies.

Materials and Methods

A systematic review was conducted to identify peer-reviewed publications related to the human microbiome and cancer. The review considered the recommendations of the Meta-analysis of Observational Studies in Epidemiology (MOOSE) group (21) and followed the Preferred Reporting Items for Systematic Reviews and Metaanalyses (PRISMA; ref. 22). A protocol (Prospero registration number: CRD42018105860) was prepared following these guidelines (22).

Eligibility (inclusion and exclusion) criteria considered in this review

Type of studies

Studies that utilized the following designs were considered for inclusion:

- (i) Observational studies: case-control, including case-crossover design or cohort studies.
- (ii) Interventional studies: Randomized Controlled Trials (RCT).

Reviews, case reports, and other studies without a comparison group, cross-sectional studies, reports from conferences or annual meetings, editorials, opinions, *in vitro* studies and studies of animals were excluded from this review. Studies not written in English were also excluded from this review.

Type of participants

This review focused on adult humans with or without any type of cancer. Studies focusing on children (<18 years) were excluded.

Type of outcome and exposure measurements

Studies investigating the prevalence or incidence of cancer and its association with the human microbiome were considered for inclusion. Our primary interest was cancer development and not cancer survival/mortality. Studies investigating only precancerous lesions/conditions (no malignant conditions) were excluded.

Studies that target specific microbes (e.g., *Helicobacter pylori*) instead of studying a microbiome (community of microorganisms) were also excluded. Next-generation sequencing approaches, including 16S ribosomal RNA gene amplicons and genome shotgun metagenomics, are the most common methods for investigating communities of microorganisms. However other methods such as aerobic and anaerobic subculturing onto selective agar media were also considered in this review, provided that communities of microorganisms were investigated. Exposures of interest were relative abundance of taxa and diversity measures (alpha and beta diversity) in cancer cases versus controls.

Data collection and analysis

Tailored search strings (see Supplementary Material Table S1) were used to search relevant articles up from database conception until December 2019 via the PubMed and EMBASE databases. Also, references in the selected publications were checked for further studies.

Selection of studies

Four investigators (A. Loobuyck and Z. Vandenbulcke for first search; I. Huybrechts and N. Michels for second search) independently

reviewed titles and abstracts. In case no consensus was reached, the article was maintained for the next selection phase (e.g., selection by full-text article). When the disagreement was still present at full-text selection ($n = 6$), the opinion of the remaining co-authors involved in this review was requested.

Data extraction

Data were extracted by three researchers independently (I. Huybrechts, N. Michels, and S. Zouiouich). Considering the important differences in outcome measures reported in the different publications, it was decided to report the significant differences in relative abundance of taxa and/or diversity measures (alpha and beta diversity) between cancer cases and controls. If multiple analyses were run with different levels of adjustment, then the one with maximal adjustment for confounders was chosen.

Methodologic quality and strength of association

Two reviewers (I. Huybrechts and N. Michels) independently assessed the methodologic quality of the included articles via the Newcastle-Ottawa quality assessment scale (ref. 23; See Supplementary Table S2). Each study was evaluated using three broad criteria: (i) appropriate selection of the study population (up to four stars); (ii) comparability of the study groups (up to two stars); and (iii) ascertainment of the exposure or outcome of interest (up to three stars). The full score was 9, and a high-quality study in our analysis was defined as a study with at least 7 points. The performance of a meta-analysis to calculate adjusted pooled estimates was ruled out because of the large variation in the definition of outcome variables and exposures. We performed instead a qualitative synthesis of results and reported them in categories according to microbiome and study design. An association was considered as “strong” when three or more publications reported a statistically significant association in the same direction and none were in the opposite direction. The association was deemed “suggestive” when two publications reported a statistically significant association in the same direction and none in the opposite direction. All analyses (e.g., counts of cases and controls and articles) were performed in Microsoft Excel.

Availability of data and material

All data generated or analyzed during this study are included in this published article (and its Supplementary Information files).

Results

Study design and population characteristics of the included studies

A total of 124 articles (including 15,764 subjects in total; 7,652 cancer cases vs. 8,112 controls) were included and used for this review (see Materials and Methods and Fig. 1: flowchart). An in-depth overview of the different studies and their study design and methods is given in Supplementary Table S3. 119 studies were case-control studies, including three nested case-control studies (24–26), and five were cohort studies (19, 27–30). No RCTs were identified. The gut microbiome was the microbiome most frequently studied ($n = 50$), followed by the oral microbiome ($n = 16$) and then some studies of the bile duct, cervical and intrauterine, esophagus and gastric, laryngeal, lung, skin, breast, urinary, and prostate microbiome (see Table 1).

Thirty-nine of the studies were conducted in North America (n subjects = 5,999), 5 in South America (n of subjects = 300), 53 in Asia (n subjects = 6,783), 27 in Europe (n subjects = 2,485), 2 in Africa (n subjects = 124) and one in Australia ($n = 83$). The year of

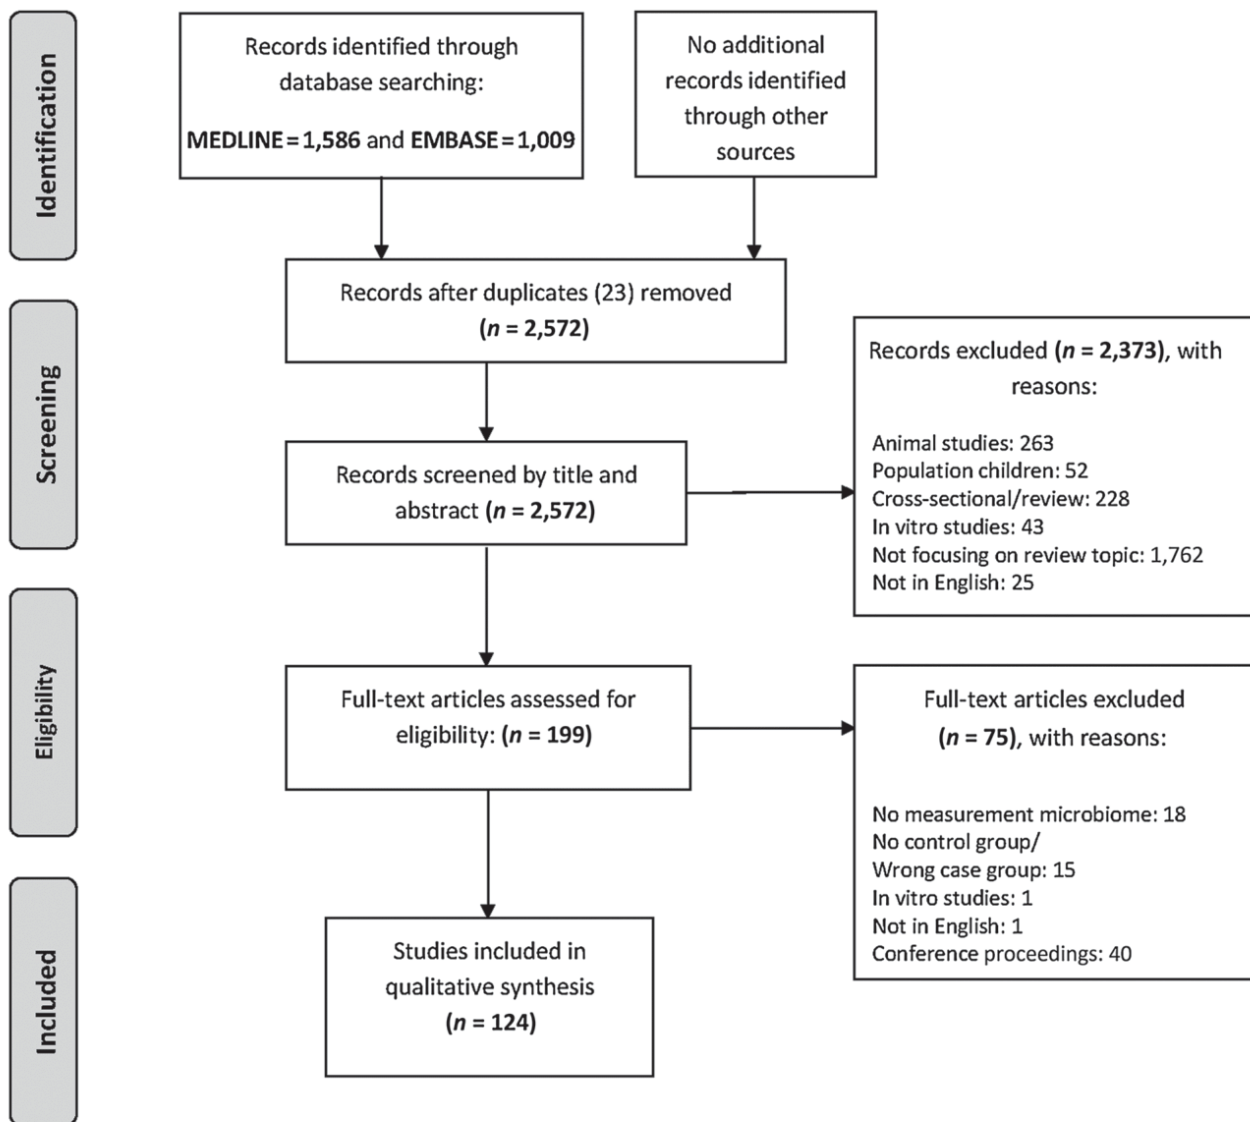

Figure 1. PRISMA flow diagram. Adapted from: Moher D, Liberati A, Tetzlaff J, Altman DG, The PRISMA Group (2009). Preferred Reporting Items for Systematic Reviews and Meta-Analyses: The PRISMA Statement. *PLoS Med* 6(7):e1000097. doi:10.1371/journal.pmed1000097. For more information, visit www.prisma-statement.org.

publication ranged from 1983 to 2019. The sample size of the studied populations showed large variation. Four articles had a sample size smaller than 10, 17 articles had a sample size ranging from 10 to 29, 27 articles had a population size from 30 to 49, 32 articles included a population size from 50 to 99, and 46 articles studied over 100 subjects. The largest number of subjects was included for the gut microbiome in relation to colorectal cancer risk ($n = 5,761$), followed by the oral microbiome–oral cancer associations ($n = 1,912$), and the oral microbiome–pancreatic cancer associations ($n = 1,729$). All studies included a population with an overall age ranging from 18 to 96 years old. In most of the studies, the cases tended to be slightly older than the healthy controls.

Quality of the studies

The methodologic quality assessments are presented in Supplementary Table S4. Eighty-eight articles had a good quality score of 7/9 or more of which 51 articles with a total quality score above 8 and two

articles reaching the maximum score of 9 stars. For selection, 70 articles received the maximum score, (31), while the most frequent problem was lack of information about the selection of cases and controls and thus their representativeness for the community. For comparability, 82 articles scored the maximum score, while other articles often did not perform any correction for confounders between cases and controls of any kind. This decreases the comparability between the patient group and the healthy controls. For exposure, 20 articles received the maximum score, while low scores were mostly because the studies used another method of ascertainment between cases and controls (e.g., resection for cases while biopsy for controls).

Overall significant findings

As demonstrated in **Table 1** and Supplementary Table S4, a large number of samples from different anatomic sites have been investigated in relation to different cancer types. Supplementary Table S5 gives an overview of the different bacteria described in these

Table 1. Number of articles retrieved by microbiome type and the possible links with cancer.

| Microbiome | Linked with the following cancer(s) | Articles, <i>n</i> | Subjects, <i>n</i> | | |

^aTwo articles included several cancers and as such were included twice in the table, namely for each cancer site. As such, the sum of the different articles based upon cancer site is higher (126) than the total number of articles used in this review (124).

studies and their direction of association with (site-specific) cancer risk. Some of the alterations in the site-specific microbiota were consistent between studies while others were only significant in one study or conflicting between studies (see also overview of significant findings for each study included in this review in Supplementary Table S4).

In addition, study results were not always comparable due to high heterogeneity in outcome definitions. Many of the articles used different parameters to describe and compare the microbiome including: alpha diversity, beta diversity, relative abundance, absolute abundance, presence/absence of taxa, and some articles clustered microbiota into communities or calculated ratios for the abundance of two microbiota taxonomic groups. Furthermore, the taxonomic level reported differed between articles (mainly the phyla, the families and genera were studied) and some of the articles showed no significant differences in presence and relative abundance of certain phyla while they did show differences at lower taxonomic levels. For example, one study (32) found the same five most abundant phyla within the cases with esophageal cancer or dysplasia and the healthy controls, but different abundances of the orders Clostridiales and Erysipelotrichales. Finally, there are also many different measures and statistical methods used to analyze alpha and beta diversity what often limits the comparability of studies reporting these diversity measures.

Because of the large amount of data presented in the different studies included in this review, we have focused on results for which at

least two studies reported findings (e.g., diversity measures or taxa) in the same direction in the description below (and visualized in **Table 2**). A full overview of the results found in the different studies is given in the Supplementary Table S4 and the study design of the included studies is presented in Supplementary Table S3.

Cholangiocarcinoma has been investigated in relation to the bile duct microbiome in two articles (33, 34), although one article only focused on the extrahepatic variant. Both studies reported microbiome differences between cases and controls, although not for the same operational taxonomic units (OTU) and a clear separation between cases and controls when analyzing beta diversity.

Two studies investigated the breast tissue microbiome in relation to invasive breast cancer (using benign breast disease as controls), reporting increased relative abundance of certain genera, although these differed between the two studies. Increased abundance was reported in the following low-abundant family and genera in the breast tissue of women with invasive breast cancer: Unclassified Bacteroidetes, Comomonadaceae Enterobacteriaceae, *Bacillus* and *Staphylococcus* (35), *Fusobacterium*, *Atopobium*, *Hydrogenophaga*, *Gluconacetobacter*, and *Lactobacillus* (unadjusted $P < 0.05$; ref. 36). In both studies, microbial diversity was not considered.

Three studies investigated associations between the cervical microbiome and cervical cancer risk. Conflicting results were found for *Lactobacillus iners*; however, all studies reported a decrease in

Table 2. Summary table presenting associations between microbiome composition and colorectal [number of studies (*n*) = 50] and oral cancer risk (*n* = 16).

^aExample *n* (%): 10 and 2 studies for Fusobacteria for colorectal cancer and oral cancer, respectively, so 20% and 13% of the total number of studies on colorectal cancer and oral cancer.

- **Strong positive association:** (≥3 publications in same direction; none in opposite direction)
- **Suggestive positive association:** (2 publications in same direction; none in opposite direction)
- **Strong negative association:** (≥3 publications in same direction; none in opposite direction)
- **Suggestive negative association:** (2 publications in same direction; none in opposite direction)

abundance of the beneficial *Lactobacillus crispatus* in cervical cancer cases (37, 38). All three studies also suggested higher alpha-diversity (Shannon index and/or OTU number) among cervical cancer cases compared with controls (37, 38, 39).

One study investigated esophageal cancer risk in relation to the esophageal microbiome (40) while another study investigated its association with the gastric microbiome (32). No significant differences were found between the esophageal microbiome of the patients with esophageal cancer and the healthy controls with no evidence of esophageal disease (40). Differences were found in the gastric microbiome composition between controls and cases with esophageal cancer on the order, family, and genus level, though the abundances were different and not always in the same direction in the two studies (32, 41). Microbial diversity was considered in one study, in which

the number of bacteria between cases and controls was not significant (40).

Ten studies investigated associations between the gastric microbiome and gastric cancer risk (42–51). The gastric microbiome of the cases with gastric cancer showed a significant difference compared with control subjects and in the cancer tissues compared with the adjacent normal tissue in the same patient with cancer. Three studies showed an increased abundance of Fusobacteria among patients with gastric cancer or cancer tissue samples (44, 47, 52) and two studies an increased abundance of Neisseria among patients with gastric cancer when compared with control subjects (46, 47). In two of these studies, the analysis of microbial diversity was included, showing a trend to diminish going from nonatrophic gastritis to intestinal type of gastric cancer (42, 47).

Seven studies evaluated associations between the airway-lung microbiome and lung cancer risk, using different methodologies [e.g., sputum samples (53, 54) vs. exhaled breath condensate and bronchial brushing (29, 30, 55–57)]. All studies demonstrated clear differences between the microbiome samples of patients with lung cancer in comparison with healthy controls, though different taxa were studied (Carpagnano only focused on *Aspergillus* species). *Streptococcus* were increased among patients with lung cancer in three studies (30, 54, 56).

Thirty-four studies investigated associations between the oral microbiome and several cancers, of which 16 considered the association with oral cancer (27, 31, 58–71) and five with pancreatic cancer (24, 72–74). The sixteen studies considering the associations between the oral microbiome and oral cancer risk obtained inconsistent results. Consistent results have been visually presented as strong or suggestive positive/negative associations in **Table 2**. From the 19 studies that reported results on the phylum *Bacteroidetes*, three studies confirmed a significant positive association between *Bacteroidetes* abundance and oral cancer risk. Similarly, four studies confirmed a positive association between the abundance of the genus *Fusobacterium* and oral cancer risk. Several studies also observed an altered abundance of *Streptococcus* in patients with oral cancer versus controls (27, 31, 58–60, 67, 69) with four studies confirming a significant negative association between *Streptococcus* abundance and oral cancer risk. Furthermore, six studies reported an altered abundance of *Prevotella*, but results differed in the direction of the association. Two of the five studies investigating associations between the oral microbiome and pancreatic cancer risk reported consistently a lower abundance of *Neisseria* in the oral microbiome of pancreatic cancer cases compared with controls (72, 73). Two studies found a lower abundance of *Neisseria* and *Haemophilus* when investigating the tongue coating samples of patients with colorectal, lung, and gastric cancer compared with controls (75, 76). Among the 34 studies analyzing the oral microbiome, 13 studies presented results on the microbial diversity and most of them showed a significant lower bacterial diversity than the healthy controls.

Two studies investigated associations between the urinary microbiome and bladder cancer risk (77, 78). Both studies reported a decreased abundance of *Streptococcus* and Bucevic reported also increased abundance of *Fusobacterium* among patients with bladder cancer. Bi and colleagues also reported a higher alpha diversity among patients with bladder cancer.

Fifty studies linked differences in the gut microbiome with colorectal cancer, three with breast cancer risk (79–81) and two with gastric cancer risk (82, 83). Thirty-three articles used fecal samples as a proxy for the gut microbiome, while 22 articles used mucosal biopsies. Three articles investigated both feces and mucosal biopsies (84–86). To compare within consistent specimen types, use of fecal samples or mucosal samples is clearly specified in the description of the results regarding associations between the gut microbiome and colorectal cancer risk here below. A summary of the strong and suggestive associations reported for the gut microbiome in relation to colorectal cancer risk has been visualized in **Table 2**.

The phylum *Fusobacteria* was more often detected in colorectal cancer tumor biopsies compared with adjacent normal tissue (25, 87–89). Seven studies also found significantly higher levels of the genus *Fusobacterium* in mucosal samples of colorectal cancer cases in comparison with controls (25, 84, 86, 88–92). In five studies, the species *Fusobacterium nucleatum* was enriched

in mucosal samples in colorectal cancer cases (85, 87, 93–95). Thirteen studies also detected a significant enrichment of the genus *Fusobacterium* in fecal samples of patients with colorectal cancer (19, 52, 96–106).

Eight studies found that the genus *Porphyromonas* was significantly enriched in fecal samples of patients with colorectal cancer compared with controls (96, 99–102, 104–107).

Two studies showed that *Lactobacillus* was significantly more present in fecal samples from colorectal cancer cases compared with controls, while the studies of Mira-Pascual and colleagues and Ohgashi and colleagues found nonsignificantly higher abundance of *Lactobacillus* in controls (85, 108–110).

The genus *Prevotella* was more commonly detected in fecal samples of colorectal cancer cases compared with controls in the study of Amiot and colleagues and two other studies reported the same trend (85, 108, 109). *Peptostreptococcus* had significantly higher abundance in fecal samples from colorectal cancer cases compared with controls in five studies (52, 84, 100, 101, 104, 110). Two studies also found a significant increase of *Peptostreptococcus* in colorectal cancer tissue compared with healthy controls (84, 88).

Six studies demonstrated an increased abundance of *Parvimonas* in colorectal cancer cases (52, 95, 97, 100, 101, 105) and three studies a significantly higher presence of *Gemella* and *Leptotrichia* in fecal samples of colorectal cancer cases compared with controls (25, 84, 91, 100, 101).

In the Spanish cohort of Allali and colleagues *Blautia* was significantly more abundant in adjacent normal tissue compared with colorectal cancer tumor biopsies and Chen and colleagues also observed higher *Blautia* levels in healthy controls compared with colorectal cancer cases (25, 84).

At the family level, *Ruminococceae* and *Lachnospiraceae* were significantly more abundant in controls and/or adjacent/“off-tumor” mucosae compared with colorectal cancer tumor samples in four and six studies, respectively (84, 90, 91, 95, 104, 106, 111, 112).

In summary, the most consistent findings for the gut microbiome were for *Fusobacterium* (most important species *Fusobacterium nucleatum*), *Parvimonas*, *Porphyromonas*, and *Peptostreptococcus* being significantly enriched in fecal and mucosal samples from patients with colorectal cancer compared with controls or adjacent normal tissue.

Among the 50 studies investigating associations between cancer risk and gut microbiome composition, results on microbial diversity were often reported. While findings on alpha diversity were inconsistent (2, 25, 52, 84, 85, 87, 89, 90, 92, 96, 97, 100, 101, 108, 110, 113, 114), five studies on colorectal cancer found significant results for beta diversity (84–86, 98, 100).

Three articles had investigated associations between the gut microbiome and breast cancer risk using a case-control design. All three studies reported microbiome differences between breast cancer cases and controls, although not for the same operational taxonomic units (OTU). The Shannon index was significantly lower in breast cancer cases and the beta-diversity was significantly different between cases and controls (79, 80).

Discussion

In total, 124 studies have been included in this systematic review to evaluate the relation between the human microbiome and cancer. The gut microbiome was the microbiome most frequently studied, followed by the oral microbiome and then studies of the bile duct, cervical, and intrauterine, esophagus and gastric, laryngeal, lung, skin, breast,

urinary and prostate microbiome. The quality assessment demonstrated rather low quality for the “ascertainment of the exposure of interest” because studies often used different methods of ascertainment for cases and controls, for example, resection for cases while biopsy for controls. The large diversity of parameters used to describe the microbial composition made it impossible to harmonize the different studies in a way that would allow meta-analysis. All articles, apart from one, showed specific differences in microbiome distribution between cases and controls. Some findings were consistent between studies while others were conflicting or only reported in one single study (see Supplementary Table S5).

Concerning the esophageal microbiome, two studies investigated different populations with other sample types, and reported different results, though both found positive associations between *Corynebacterium* and *Peptococcus* in the mouth and esophageal cancer risk. Bacteria from the *Corynebacterium* and *Peptococcus* genera represent an important component of skin and mucosal membranes, being part of the oral and upper respiratory tract microbiome and exist through commensal interactions with their hosts (115, 116). However, some species from the *Corynebacterium* genus can act as opportunistic pathogens and secrete exotoxins associated with a number of diseases such as diphtheria, pleuropneumonia, and sepsis (115). Similarly, *Peptococcus*, a Gram-positive anaerobic coccus, has been observed to be enriched in different infections such as periodontitis and in wounds such as chronic ulcers (116). Immunocompromised patients with cancer patients might be privileged targets for these opportunistic pathogens. More research and standardized protocols for sample collection are needed to clarify this potential link between the esophageal microbiome and cancer risk.

Many bacteria can be found in the human oral cavity and these are not only associated with oral cancers but also with cancers of the lung, the esophagus, the stomach, the pancreas and the colorectum. While the oral microbiome has been suggested to play a crucial role in carcinogenesis, the oral microbial community is complex and may be impacted by many other environmental and genetic factors and potentially due to this complexity, published research has often shown inconsistent results. However, some potential pathways have been suggested for the putative role between the oral microbiome and cancer risk. For instance, the observed decrease of *Streptococcus* in precancer and oral cancer cases might reflect early changes of the oral mucosa surface related to tumorigenesis (31, 58). Indeed, *Streptococci* might lose their ability to adhere to mucosa undergoing tumorigenesis while other species, such as *Fusobacterium*, which are often increased in oral cancer cases (58) might adhere better. *Fusobacterium nucleatum* is reported to activate the nuclear translocation of NF κ B leading to a proinflammatory environment. However, this translocation is inhibited by *Streptococcus* thus attenuating the proinflammatory responses induced by *Fusobacterium*. This suggests that a decrease of *Streptococcus* combined with an increase of *Fusobacterium* might play a role in oral cancers (117). In the gut, *F. nucleatum* is associated with colorectal cancer, potentially because it might increase reactive oxygen species (ROS) and IL10 production leading to an inhibition of the T cells and the antitumor immunity (118). Furthermore, some *Streptococci* can inhibit the oral colonization of certain bacteria such as *Aggregatibacter actinomycetemcomitans*, *Prevotella intermedia*, and *Porphyromonas gingivalis* on the oral epithelial surfaces (117). This highlights the importance of interactions between the bacteria themselves and the human mucosa (117).

The gut microbiome was analyzed in both fecal and colorectal mucosal samples. In general, fecal samples had a higher microbial diversity when compared with tissue-associated microbiomes. The results included in this review clearly demonstrate that gut microbiota composition differ between patients with colorectal cancer and noncancer. The most consistent findings were for *Fusobacterium* (with most important species *Fusobacterium nucleatum*), *Parvimonas*, *Porphyromonas*, and *Peptostreptococcus*, which were significantly enriched in both fecal and mucosal samples of patients with colorectal cancer compared with controls across multiple studies. Several of our reviewed articles and a recent meta-analysis (119) reported that *Fusobacterium nucleatum*, already known as an invasive and proinflammatory agent that can cause acute and chronic oral and gastrointestinal infections, was significantly enriched in both fecal and biopsy samples of colorectal cancer patients. With its unique FadA adhesin, *Fusobacterium nucleatum* adheres to, invades, and induces inflammatory and oncogenic responses to stimulate growth of colorectal cancer cells (120). Another study suggested that *Fusobacterium nucleatum* induces NF κ B to promote colorectal cancer (98). Alternatively, *Fusobacterium* may act as a “passenger” that multiplies in the more favorable conditions caused by the malignant tumor rather than itself being a causal factor in colorectal cancer development (103).

Species of *Parvimonas* were consistently reported with elevated abundance in colorectal cancer tumor biopsies. *Parvimonas micra*, the only species described at the genus level, is known to cause bacteremia, abdominal abscesses, endocarditis, and other infections (95). Its tumor-promoting effect has been suggested to be associated with altered immune responses and enhanced inflammation in the gut (121).

Previously, it has been shown in malignant and primary human oral epithelial cells that *Porphyromonas gingivalis* and its membrane fraction induces upregulation of a number of genes involved in inflammation and cell proliferation and control (122); however, specific data for colorectal cancer are lacking.

A possible explanation for the higher abundance of *Peptostreptococcus* species in patients with colorectal cancer could be due specifically to the presence of *Peptostreptococcus anaerobius*. *P. anaerobius* has been shown to promote colon dysplasia in a mouse model, specifically interacting with TLR2 and TLR4 on colon cells to increase levels of reactive oxidative species, which promotes cholesterol synthesis and cell proliferation (123).

Overall, many other differences in the abundance of certain bacteria were found between cancer cases and controls, although often not consistent between studies. Differences in results could partly be due to variation in study design and methods used such as tissue sampling (different method or different site), techniques used to characterize the microbiome, or different study populations (e.g., genetic and environmental differences including nutritional intakes and habits, oral hygiene, air pollution etc.), exclusion criteria, or other unrecognized factors. Furthermore, the microbiome may differ depending on tumor stage which could also be a cause of inconsistent results if stage was not considered in the analysis.

Barriers and challenges in microbiome studies

The number of epidemiologic studies that investigate the association between the human microbiome with cancer risk is rising; however, it is challenging to obtain definitive and high quality evidence. First, it remains difficult to establish the causality of the cancer–microbe associations (2, 16). When a bacterium is enriched at a tumor site, there are other possible reasons for that association

besides a causal relation. For example, the microbe can take advantage of the tumor's oxygen tension or carbon sources, or find an underused nutritional niche where they can grow freely (16). It is not clear whether the carcinogenic process changes the local environment and creates new niches for microbes, or if an alteration of the microbial composition and its function contribute to carcinogenesis. As such, reverse causation is an important concern (2). Given that many of the previous studies use a case-control design, prospective studies are urgently needed to help understand the temporal nature of the association between the microbiome and cancer development.

Another challenge is that different microbes might contribute to different stages of carcinogenesis (6, 16, 17). In the initiation stage, the microbiome may promote specific genetic mutations and chronic inflammation, but may also be involved in creating other tumor-promoting environments such as the development of obesity and the metabolic syndrome (6). After the initiation phase, other microbiota could be responsible for tumor growth, angiogenesis, and metastasis (6, 16). Because cancer development is a process that continues over many years, it is possible that by the time the cancer is diagnosed, the initial causal microbes are no longer present due to the later stage tumor environment (16, 17).

It is also unlikely that many of these cancers are due to an undetected "one microbe-one disease" association (17). It is well established that *H. pylori* infection causes gastric cancer and there are nine other microorganisms that are designated by the International Agency for Research on Cancer to be carcinogenic to humans (16, 17). However, some microbes might have modest and subtle contributions to cancer development, which will be harder to detect. It is also likely that some of those modest contributions depend on the genetic background of the host, sex, and age; as well as lifestyle and other environmental exposures (2, 17).

In addition, the microbiome composition at one specific anatomic site may be related with cancer development localized elsewhere (e.g., relationship between oral microbiome and pancreatic cancer risk; refs. 24, 72, 73), making it complex to investigate causal relationships. Indeed, symbiotic bacteria, especially in the gut, are able to influence host metabolism through producing and modifying a plethora of biologically active compounds, including hormones, carbohydrates, and lipids that reach the systemic circulation. For instance, high concentrations of secondary bile acids, derived from host-produced primary bile acids, were associated with increased risk for colorectal, pancreatic, and liver cancer (124–126). Another example is the important role of indole derivatives, produced by gut bacteria from the degradation of tryptophan, such as aryl hydrocarbon receptor ligands, to maintain intestinal homeostasis, limit inflammation and thus, indirectly reduce the risk of colorectal, prostate and breast cancer (127–129). Finally, short-chain fatty acids are produced by the gut microbiome through fermentation of nondigestible fiber and starch and help maintain balance between intestinal immunity and inflammation (130, 131). As such, microbiota may influence the risk of many cancers, independent of anatomic location due to effects of microbial metabolites on inflammation, an important hallmark of cancer, and other metabolic conditions associated with cancer risk.

Finally, the study design and methods used may limit the validity, generalizability and comparability of results. Because many exogenous and intrinsic host factors influence the human microbiome (>125 factors collectively explain 18.7% of the variation in human gut microbiome composition; ref. 132), a large sample size and an important battery of information on host factors are needed to

investigate potential causal relationships between the human microbiome and cancer risk with sufficient statistical power. Furthermore, restrained physical access to certain body sites limits the possibilities for large-scale sample collections. For example, to avoid invasive procedures such as biopsy, other specimen available for studies of prostate cells such as expressed prostatic secretions or urine samples containing prostatic cells are often used (133, 134). In addition, different sample handling/storage strategies (e.g., room temperature storage versus immediate freezing, different collection media, etc.; refs. 135, 136), laboratory methods, sterilization procedures, sequencing strategies (e.g., 16S rRNA gene or shotgun sequencing), and various processing pipelines for the raw sequencing data, can all impact the comparability of different studies (137). Indeed, the techniques used to characterize the microbiome composition may also importantly impact the quality of the results. While bacteriological cultures (in 8 of the 124 included studies) only allow the analysis of certain specific communities of microorganisms as (e.g., <30% of gut microbiota have been cultured to date), most studies were based on sequence analysis of the 16S rRNA gene, which is sufficiently divergent to provide a phylogenetic signal and identification of unknown bacteria. More recent culture-independent techniques such as next-generation sequencing have the advantages that they are high throughput, phylogenetically characterize the microbiota components, and quantify the relative proportions of organisms present (138). In addition, for determining alpha and beta diversity, there are many different measures and statistical methods that have been used that may further limit comparability between studies. Gail and colleagues are currently working on a method to have a reference-based distance for beta-diversity to be able to combine beta diversity analyses across studies in future (139).

Multi-omics analysis (140) could potentially assist in disentangling complex relationships between the human microbiome and cancer risk by integrating the microbiome data with other omics data of interest for investigating causal factors of cancer development. However, microbiome multi-omics data analysis remains challenging as few tools exist to integrate these data. Current statistical approaches, such as correlation tests between microbiome taxa and specific host metabolites, do not necessarily meet the assumptions of the sparse compositional nature of microbiome data (141, 142).

Limitations of our review

A limitation of our review is that tumor stage and grade were not considered because of limited evidence in the studies included in this systematic review. Different stages of the cancer might harbor different microbiomes and this could be a cause of nonconsistent results across studies. Tumor severity has been shown to have an impact on microbiome composition (85). On the other hand, another study reported that the gut microbiome did not change as the cancer progressed and that any change might have occurred in the early stage of carcinogenesis (108). On the basis of these opposing findings, it would be important to further investigate whether tumor stage has an impact on the composition of the microbiome.

Another limitation is that the location of the colorectal cancer tumors was not considered although differences in microbiome composition between distal and rectal versus proximal cancers have been shown (86). In addition, microbiome composition in the colorectum can also be influenced by bowel cleansing which is not considered in every study and which was not part of our exclusion criteria.

The microbiome of patients from different countries was also compared with one another (see Supplementary Tables S3 and S4). The study of Allali and colleagues showed significantly higher phylogenetic diversity in tumor and adjacent tissues from patients of the United States compared with a Spanish cohort (25). So it is not certain whether gut microorganisms linked to cancer are the same across different countries and populations.

As mentioned above, we compared studies that made use of different techniques to characterize the gut microbiome. These different techniques may lead to different findings. Every study has its own exclusion criteria and although many studies matched their cases and controls for age, sex, body mass index (BMI), and other factors there are some differences in potential confounding variables across reviewed articles, which may have impact on our findings (see Supplementary Tables S3 and S4). Specific study design issues should be considered when conducting longitudinal studies for microbiome research (143). Biological sample collection, processing (DNA extraction, amplification, sequencing, and bioinformatics) and storage as well as quality control standards still require improvement. At the same time, guidelines need to be elaborated to report results and share data to ensure replication and reproducibility of these studies (143).

Finally, a limitation of this review is the lack of quantitative results from meta-analysis due to substantial heterogeneity in the microbiome parameters assessed.

Clinical implications and future perspectives

This review has shown some specific microorganisms appear to have a different prevalence in cancer cases than in controls. Tumor stage was not considered so it is not clear whether these specific microorganisms are present from the initiation of carcinogenesis. Therefore, more research, in particular via prospective studies, is needed to investigate if the microbiome could be a potential tool for cancer early detection and/or prevention strategies. Few studies already indicated that the gut microbiome, with its specific microorganisms could potentially be used as an effective tool in early screening for colorectal cancer (113).

Knowledge on microorganisms linked to cancer may also play an important role in cancer therapy. There is limited evidence suggesting that dysbiosis of the gut microbiome can be improved using probiotic and prebiotic supplementations in children with cancer (144). There is limited evidence for cancer prevention, but it is used for many other health outcomes such as improved digestion (17).

More understanding of the specific roles of the microbiome is required before promoting the microbiome as an adjuvant therapy that enhances efficacy or attenuates the toxicity of chemotherapies (6, 16). Herein, stronger evidence derived from studies with more optimal study design and methods and from different geographic regions is needed. To detect strong associations between microbiome profiles and various types of cancer, adequate power could be reached by pooling or meta-analyzing data across multiple studies. However, heterogeneity of data hinders meta-analysis. Therefore, standardization across studies is needed. Future prospective studies should coordinate and collect fecal samples using at least one common method in addition to the method of their choice. Recent studies have evaluated multiple fecal and oral sample collection methods and a variety of methods appear to be reproducible, stable, and accurate compared to an immediately frozen fecal sample. (145–147). DNA extraction and

sample handling were also reported to contribute to variability in microbiome data (135, 136), it is therefore important for future studies to use standardized methods including negative and positive controls at all stages of sample processing and, when possible, use automation when processing samples. To have homogeneity of data, data analysis methods need to be transparent, consistently reported and reproducible, which still remains a major challenge in current microbiome reports. Microbiome bioinformatics platforms such as Quantitative Insights Into Microbial Ecology 2 (QIIME 2; refs. 148, 149) improve reproducibility of bioinformatics analysis by providing automated, decentralized data provenance tracking. Another bioinformatics challenge for future prospective studies is the low access to long-term archives of raw microbiome sequence data with sample and study metadata in common formats (150). Finally, future study designs should focus on the assessment of potential confounding factors by collecting high-quality clinical and nutritional data that are known to influence the microbiome.

Conclusions

Although strong evidence was available for certain taxa of the gut microbiome and colorectal cancer risk, and for the oral microbiome and oral cancer risk, for most of the microbiome taxa/indicators the evidence was still too weak to draw firm conclusions in relation to their role in cancer. In addition, based on the state of the field, it is currently not possible to have an overall ascertainment of cancer risk due to the microbiome because the data generated is heterogeneous and merging studies for meta-analysis is extremely difficult. Therefore, future prospective studies with prediagnostic specimen collection using standardized methods, consistent laboratory methodology and bioinformatics, and inclusion of quality control samples are required to establish causal links. Also “integromics” analysis (integrating microbiome data with other –omics data; e.g., metabolomics, epigenomics) may further assist in disentangling these complex relationships between the human microbiome and cancer risk although these will require significantly increased sample sizes and likely pooling across multiple cohorts.

Disclosure of Potential Conflicts of Interest

N. Michels reports grants from Research Foundation Flanders (FWO) during the conduct of the study. No potential conflicts of interest were disclosed by the other authors.

Chapter III: Markers of metabolic health and gut microbiome diversity: findings from two population-based cohort studies

1. Background

While the gut microbiome has been hypothesised to influence insulin resistance and chronic inflammation development (93,94,107,108), human data on insulin resistance and other metabolic parameters and the gut microbiome are still limited as very few cohorts have collected both blood and fecal specimens. Insulin resistance and inflammation lie on the causal pathways of diabetes and other metabolic diseases, and are established risk factors for colorectal cancer (118–120), and therefore, deciphering the pathophysiology of insulin resistance and inflammation using population-based data might help to understand the mechanisms of colorectal cancer development and strengthen evidence for potential preventive strategies.

2. Objective

The aim of this study was to investigate the association of gut bacteria 16S rRNA gene sequence data with serologic levels of homeostatic model for insulin resistance (HOMA-IR), glycated haemoglobin (HbA1c) and C-reactive protein (CRP) in two distinct population-based cohorts, the Northern Finland Birth Cohort 1966 (NFBC) and TwinsUK.

3. Methods

Study design and samples

This study was carried out among 506 participants from the NFBC and 1,140 participants from TwinsUK. In the NFBC, at age 46 years, anthropometric measures, including body mass index (BMI), and lifestyle information were collected using self-administered questionnaires and clinical examinations. All the metabolic markers were measured during clinical examination after an overnight fasting period of 12 hours. Additionally, at 46 years of age, the participants were asked to collect a fecal sample at home. In TwinsUK, height and weight were measured during each participant's annual clinic visit, allowing BMI to be calculated. Smoking status was obtained by

questionnaires. Glucose and insulin levels were measured for all individuals after a 10 hours overnight fast. TwinsUK participants were also asked to collect a fecal sample at home and bring it to the clinical research facility. In both cohorts, HOMA-IR was calculated based on fasting insulin and fasting glucose levels. The gut microbiome was characterized using the same procedure in both cohorts. DNA was extracted using MO-BIO PowerSoil® kit, and the V4 region of the 16S rRNA gene was amplified and sequenced using the MiSeq. The sequence quality control was performed with QIIME2 and DADA2, and diversity metrics calculated using R.

Statistical analysis

We estimated associations between gut microbiome diversity metrics and serologic levels of HOMA-IR, glycated haemoglobin HbA1c and C-reactive protein CRP using multivariable linear regression models adjusted for gender, smoking status and BMI. We used general linear models with a quasi-Poisson distribution and Microbiome Regression-based Kernel Association Tests (MiRKAT) to estimate associations of metabolic parameters with alpha- and beta-diversity metrics, respectively, and generalized additive models for location scale and shape (GAMLSS) fitted with the zero-inflated beta distribution to identify taxa associated with the metabolic markers.

4. Results

Overall, increased levels of HOMA-IR and CRP were associated with decreasing richness or diversity of microbiome composition in the two cohorts. Most importantly, the relationship between high levels of metabolic parameters and lower microbiome diversity was still significant, even after adjustment for BMI. In addition, in the NFBC, the association of BMI and microbiome diversity was attenuated when adjusting the model for insulin resistance. Finally, the beta component of the zero-inflated beta regression model indicated associations between HOMA-IR, CRP and HbA1c with several bacteria at the genus level.

5. Conclusion

Our findings indicate, in two distinct population-based cohorts, that individuals with worse metabolic control have lower gut microbial diversity and may provide insight into the pathophysiological mechanisms that underlie poor metabolic health. However, due to the cross-sectional nature of this study, it is impossible to conclude if these

differences in microbial composition and taxa associations are a cause or a consequence of metabolic dysfunction.

Abstract

Aims/hypothesis: The gut microbiome is hypothesized to influence development of insulin resistance and other metabolic parameters, however, data from population-based studies are limited. We investigated associations between serologic measures of metabolic health and the gut microbiome in the Northern Finland Birth Cohort 1966 (NFBC1966) and in TwinsUK.

Methods: Among 506 individuals from the NFBC1966, with available fecal microbiome (16S rRNA gene sequence) data, we estimated associations between gut microbiome diversity metrics and serologic levels of homeostatic model for insulin resistance (HOMA-IR), glycated haemoglobin (HbA1c) and C-reactive protein (CRP) using multivariable linear regression models adjusted for gender, smoking status and body mass index (BMI). We used general linear models with a quasi-Poisson distribution and Microbiome Regression-based Kernel Association Tests (MiRKAT) to estimate associations of metabolic parameters with alpha- and beta-diversity metrics, respectively, and generalized additive models for location scale and shape (GAMLSS) fitted with the zero-inflated beta distribution to identify taxa associated with the metabolic markers. Associations between gut microbiome diversity and HOMA-IR and CRP were also investigated in 1,140 adult participants from TwinsUK.

Results: In the NFBC1966, alpha diversity was significantly lower in individuals with higher HOMA-IR with an average of 76.5 (standard deviation [SD] 18.9) sequence variants (ASVs) for the first quartile of HOMA-IR and 65.9 (SD 18.4) for the fourth quartile of HOMA-IR. Alpha-diversity was also lower with higher HbA1c (number of ASVs and Shannon's diversity, P-values <0.001 and =0.003 respectively) and higher CRP (number of ASVs, P-values=0.025), even after control for BMI and other potential confounders. In TwinsUK, alpha-diversity measures were also significantly lower among participants with higher measures of HOMA-IR and CRP. When considering beta-diversity, we found that microbial community profiles were associated with HOMA-IR in the NFBC1966 and TwinsUK, using multivariate MiRKAT models, with binomial deviance dissimilarity P-values of <0.001.

Conclusions/interpretation: Overall, higher levels of HOMA-IR, CRP and HbA1c were associated with statistically significantly lower microbiome diversity in both the NFBC1966 and TwinsUK, even after control for BMI and other parameters. These results from two distinct population-based cohorts provide evidence that individuals with worse metabolic control have lower gut microbial diversity and may provide insight into the pathophysiological mechanisms that underlie poor metabolic health.

Key words: Insulin resistance, metabolic health, HOMA-IR, fecal microbiome

Research in context

What is already known about this subject?

- Insulin resistance lies on the causal pathways of diabetes and other metabolic diseases, however, the pathophysiological origins of insulin resistance are not fully understood.
- The gut microbiome has been hypothesized to influence insulin resistance development. However, human data on insulin resistance and the gut microbiome are limited as very few population-based cohorts have collected both blood and fecal specimens.

What is the key question?

- What is the relationship between the gut microbiome and serologic measures of metabolic health in population-based studies?

What are the new findings?

- Higher levels of insulin resistance and other markers of metabolic dysfunction were associated with lower richness and/or evenness of microbiome composition in two population-based cohort studies, even after control for obesity.

How might this impact on clinical practice in the foreseeable future?

- Modification of the gut microbiota among individuals with worsening insulin sensitivity and metabolic control may offer a potential preventive strategy for Type 2 diabetes.

Introduction

Obesity and Type 2 diabetes (T2D) have reached global epidemic proportions and are recognised as major causes of morbidity and mortality (97,189). Insulin resistance is a pathophysiological condition that precedes the development of T2D (98), however its aetiology is not fully understood. Obesity is a recognised risk factor for insulin resistance but not all insulin resistant individuals are overweight or obese (99); indeed, the existence of metabolically-healthy obese and metabolically unhealthy normal-weight individuals has been described in previous studies (100). Despite the well-established epidemiological links between insulin resistance, its related parameters (i.e. poor glucose control and high levels of inflammation), and chronic diseases including obesity and T2D, the potential role of the gut microbiome in the development of insulin resistance and T2D is not fully understood.

Previous studies have suggested a link between the gut microbiome and metabolic health (94,107) and in particular, have described differences in microbial composition and functionality in T2D patients compared to healthy participants, suggesting that the microbiome may play a key role in the pathogenesis of the disease (93,94). The gut microbiome might influence host metabolic health through several pathways including energy extraction, intestinal barrier integrity, metabolism of bile acids and host metabolic and signalling pathways, which are directly or indirectly related to insulin resistance development (109). For example, circulating levels of branched-chain amino acids (BCAA) have been positively associated with insulin resistance (111) and BCAA levels in insulin-resistant individuals correlate with specific changes in gut microbiome composition and functions, such as enriched potential for BCAA biosynthesis, and deprivation of genes encoding for BCAA transport into bacterial cells (112).

Despite an important expansion of research on the role of the human gut microbiome and metabolic disorders in recent years, human data on insulin resistance from population-based studies are lacking. In this study, we investigated the relationship between measures of metabolic health (i.e., insulin resistance, glucose control and inflammation) and gut microbial diversity independent to BMI, among individuals in the Northern Finland Birth Cohort (NFBC1966) and then sought to replicate these findings in the TwinsUK cohort.

Methods

Ethics approval and consent to participate: Informed written consent was obtained from all NFBC1966 participants, and the research protocols were approved by the Ethics Committee of Northern Ostrobothnia Hospital District, Finland. A written informed consent was obtained from all the TwinUK volunteers upon registration and also during their clinical visits, and the research protocols had ethical approval as parts of the Twins UK (EC04/015) study from Local Research Ethics Committee at the Department of Twin Research and Genetic Epidemiology, King's College London. The study was approved by the International Agency for Research on Cancer Ethic Committee.

Northern Finland Birth Cohort

Study design and samples: The NFBC1966 was established in 1965 and included 12,055 mothers, with expected date of delivery between 1st of January to 31st of December 1966, and subsequently 12,058 children representing 96% of live births in two Finnish provinces, Oulu and Lapland (<https://www oulu.fi/NFBC1966/>) (190). Pregnancies were followed prospectively and children were followed through childhood, adolescence and early adulthood up to 46 years of age. At 31 and 46 years of age, information about health, behaviour, work and social background were collected using self-administered questionnaires and clinical examinations were performed. At 31 and 46 years of age, measures of metabolic health were generated using blood samples. Additionally, at 46 years of age, the participants were asked to collect a stool sample at home using a collection tube without additive that was provided by study investigators. Participants were asked to return the sample to the study facility the same day; if the specimen was taken 1-2 days in advance, the participants were asked to store the stool sample at -20°C. At the study laboratory, the stool samples were first transferred to -20°C freezers and after, to long-term -70°C freezers without any additive within days of collection. Written informed consent was obtained from all participants either via postal inquiry or clinical examination at 31-year and 46-year time points. Ethical approval for the NFBC1966 project was obtained from the Ethical Committee of the Medical Faculty of University of Oulu and Northern Ostrobothnia Hospital District.

This investigation builds upon a related study conducted by Lofffield et al within the NFBC1966, which aimed to explore associations of body mass index (BMI) history and adult BMI with fecal microbial diversity (n=565) and microbial metabolite levels (n=340) (191). In the current analysis, participants were selected from the same cohort with fecal microbial diversity data and were included if measures of metabolic health (i.e. insulin [$\mu\text{U/L}$], glucose [mmol/L], high sensitivity C-reactive protein [mg/L], and glycated haemoglobin [mmol/mol]) were available at 46 years of age. In total, 506 participants were included in our analytic sample, including 187 males (37.0%) and 319 females (63.0%).

At age 46 years, participants had a clinical examination, during which height and weight were measured, and they completed self-administered questionnaires reporting lifestyle and demographic characteristics. BMI was estimated as measured weight (kg) divided by measured height (m) squared (kg/m^2). BMI was categorized according to the WHO International Classification system: normal weight (18.5–24.9), overweight/pre-obese (25.0–29.9), obese (≥ 30.0). Smoking status was categorized into three groups: never smoker, former smoker or current smoker.

Laboratory methods: The laboratory methods have previously been described in detail (192). Metabolic markers were measured for all individuals after an overnight fasting period (12 hours). Fasting plasma glucose was analysed by an enzymatic dehydrogenase method (Advia 1800, Siemens Healthcare Diagnostics, Tarrytown, New York, USA). Fasting serum insulin was analysed by a chemiluminometric immunoassay (Advia Centaur XP, Siemens Healthcare Diagnostics, Tarrytown, New York, USA). Homeostasis model assessment for insulin resistance (HOMA-IR) is a commonly used measure of insulin resistance and is calculated as fasting insulin [$\mu\text{U/mL}$] x fasting glucose [mmol/L] /22.5 (192). HOMA-IR values were subdivided into quartiles based on its distribution across all included participants: Q₁: <1.20, Q₂: 1.20-1.91, Q₃: 1.91-3.1, Q₄: >3.11 for categorical analyses. The concentration of glycated haemoglobin (HbA1c) were measured using immunochemical assay methods. High-sensitivity C-reactive protein (CRP) was analysed by an immune-nephelometric assay (BN ProSpec, Siemens Healthcare Diagnostics, Newark, Delaware, USA). HOMA-IR, HbA1c and CRP were log-transformed for numerical analyses.

DNA extraction, amplification and sequencing: Fecal samples were processed at the University of California, San Diego (La Jolla, California). DNA extraction, PCR amplification, and sequencing were completed as described by Lofffield et al (193) , and previously by Vogtmann et al (194), using the universal bacterial primer set 515F/806R (195). In brief, study samples were randomly ordered and distributed within the batches. For technical reproducibility, replicate fecal samples from three individuals (n=62) were distributed within and across batches. Four quality control (QC) samples were also included within each DNA extraction batch: artificial community, chemostat community (196), extraction blank and PCR blank. DNA was extracted with the MO-BIO PowerSoil® DNA isolation kit and the V4 region of the 16S rRNA gene was PCR amplified and 2 × 150 bp paired-end sequencing was performed on the MiSeq (Illumina, San Diego, CA). After removing singletons and reads with read errors, the average coverage was approximately 112,000 reads per sample.

Bioinformatics: Bioinformatics processing was performed using QIIME 2 2017.8 (197). Sequences were demultiplexed, and quality control on forward reads was performed with DADA2 (23). Paired end reads were not joined, because shorter 16S rRNA gene sequences would be dropped because they cannot be joined with 150 base reads, resulting in systematic bias in community composition. Taxonomy was assigned to amplicon sequence variants (ASVs) using q2-feature-classifier (198) and the Greengenes 13_8 reference database (199). A phylogenetic tree was built by aligning ASVs with MAFFT (200), filtering highly variable positions via q2-alignment, and applying FastTree (201) to construct an unrooted tree, followed by midpoint rooting using q2-phylogeny midpoint-root. Diversity metrics (i.e Shannon index, observed sequence variants, binomial deviance dissimilarity, Jaccard, weighted and unweighted UniFrac) were computed using the “vegan” (202) and “microbiome” packages in R (version 3.6.0) at a depth of 10,000 reads per sample to represent the diversity of unique sequences in each sample. As described by Lofffield et al, inspection of QC data suggested good reproducibility within and across batches (193).

TwinsUK

Study design and samples: The TwinsUK cohort is one of the largest adult twin registries in the world comprising over 14,000 volunteers (203). In the current analysis

we analysed data from 1,140 female participants with data on the gut microbiome and both HOMA-IR and CRP.

Anthropometric and lifestyle: Height and weight were measured during each participant's annual clinic visit, allowing BMI to be calculated. Smoking status was obtained by questionnaires.

Laboratory methods: Plasma glucose and insulin were measured for all individuals after a 10 hours overnight fast. Immunoassay (Abbott Laboratories, Maidenhead, U.K.) quantified insulin and glucose was measured by Ektachem 700 multichannel analyzer using an enzymatic colorimetric slide assay (Johnson and Johnson Clinical Diagnostic Systems, Amersham, U.K), as previously described (204) and HOMA-IR was calculated. High sensitive CRP was measured by latex-enhanced nephelometry on a Siemens Prospec Nephelometer.

Microbiome: Fecal samples were collected at home and brought or sent on ice to the clinical research facility where they were stored at -80°C. Samples were then processed to determine gut microbial composition by 16S rRNA gene sequencing, as previously described (205). Briefly, the V4 variable region of the 16S rRNA was amplified and sequenced using a multiplexed approach on the Illumina MiSeq. 16S sequences were demultiplexed in QIIME. Amplicon sequencing variants were then generated using the DADA2 package in R using the pipeline as described elsewhere (206).

Statistical analyses: Descriptive characteristics of the participants (i.e. measures of metabolic health and covariates) were presented by BMI groups. Pearson and Spearman correlations were calculated to estimate correlations between the different measures of metabolic health and BMI. To estimate the association of the measures of metabolic health as categorical and numerical variables with the alpha-diversity metrics, general linear models with a quasi-Poisson distribution were used. For the association between microbial community profiles using beta-diversity metrics and the measures of metabolic health, MiRKAT tests were calculated (207). To identify the taxa associated with HOMA-IR, CRP and HbA1c, after grouping ASVs at the genus level, a generalized additive model for location scale and shape (GAMLSS) fitted with

the zero-inflated beta distribution (BEZI) was computed using the “gamlss” package in R (208). The GAMLSS-BEZI model is a mixture model with two components including a zero model accounting for excess zeros and a count model to capture the remaining component by beta regression, allowing for overdispersion effects. The first component of this mixture model is linked by the nu parameter that models the probability at zero, while the second component is indexed by the mu and sigma parameters, respectively the mean and precision parameters. Likelihood-ratio tests between models including adjustment factors only and models including the measures of metabolic health and adjustment factors were performed. P-values < 0.05 were considered as indicators of the effect of the analysed measures of metabolic health in affecting the distribution of the taxonomic component. The p-values were then corrected using Benjamini-Hochberg false discovery rate (FDR) < 0.05. All statistical tests described above were adjusted for BMI, gender and smoking status in the NFBC1966 and for BMI, age and smoking status in TwinsUK. Other confounding factors such as alcohol consumption and physical activity were considered but not selected.

Results

As presented in Table 1, the majority of NFBC1966 participants were female, and 29.2%, 45.9% and 24.9% were normal weight, overweight and obese, respectively. The TwinsUK cohort was entirely female and older compared to the NFBC1966 (mean age 62.9 and 46.6, respectively). In the NFBC1966, 31.9% of current smokers were obese against 16.5% in TwinsUK. In the NFBC1966, BMI was strongly correlated with HOMA-IR (R=0.64, 95%CI [0.58; 0.68]) and more moderately correlated with CRP (R=0.37, 95%CI [0.29; 0.44]) and HbA1c (R=0.23, 95%CI [0.14; 0.31]) (Figure S1). Compared to NFBC1966, in TwinsUK, BMI was moderately correlated with HOMA-IR (R=0.43, 95%CI [0.38; 0.47]) and CRP (R=0.37, 95%CI [0.31; 0.41]).

Prior to conducting multivariable analyses, variance inflation factors (VIF) were calculated to evaluate potential multicollinearity between alpha diversity metrics, BMI and HOMA; moderate VIF were found with these two covariates (VIF BMI 1.37, VIF HOMA-IR 1.43), suggesting that these predictors are not correlated with other variables. In NFBC1966 multivariable models that adjusted for BMI, gender and smoking status, alpha diversity was significantly reduced with increasing quartiles of HOMA-IR (Table 2). For example, Shannon's diversity was lower in the 4th quartile of

HOMA-IR (2.59, 95%CI [2.50; 2.68]) compared to the 1st quartile (2.80, 95%CI [2.71; 2.89]). Similar results were found in the TwinsUK cohort where Shannon's diversity was significantly lower in the 4th quartile of HOMA-IR (3.72, 95%CI [3.65; 3.79]) compared to the 1st quartile (3.91, 95%CI [3.84; 3.98]). Quasi-Poisson models in NFBC1966 showed significant inverse associations of alpha diversity with numerical HOMA-IR, CRP and HbA1c levels (Table 2). In the TwinsUK cohort, Shannon's diversity was significantly reduced with increasing HOMA-IR (Estimate=-0.062, P-value<0.001) and CRP (Estimate=-0.018, P-value= 0.031) as well as the number of observed ASVs. In the NFBC1966, in multivariable models including numerical HOMA-IR or CRP and BMI, the association between BMI and the number of observed ASVs was no longer significant after adjustment (P-value without HOMA-IR: 0.001, P-value in model including HOMA-IR: 0.489, P-value in model including CRP: 0.082) (Table S1). In multivariable models including HbA1c and BMI, the association between BMI and the number of observed ASVs remained significant. In the TwinsUK cohort, BMI remained strongly inversely associated with alpha diversity, regardless of the presence of HOMA-IR or CRP in the model (Table S1).

In the NFBC1966, using the first three PCoA vectors from four beta diversity matrices, no visual clustering was observed by measures of metabolic health (results not shown). In the NFBC1966, when considering community composition using measures of beta-diversity, significant differences were detected by numerical HOMA-IR, CRP and HbA1c for three measures (e.g. binomial, Jaccard, Unweighted UniFrac) in adjusted MiRKAT models (Table 3); however, no association was seen for weighted UniFrac. In the TwinsUK cohort, similar results were found with significant differences detected by numerical HOMA-IR for three measures (e.g. binomial, Jaccard, Unweighted UniFrac) but not for weighted UniFrac. However, by numerical CRP, a significant difference was observed only for Jaccard. In MiRKAT models including BMI with adjustment only for gender and smoking status in the NFBC1966 and for age and smoking status in TwinsUK, the associations with BMI were significant for binomial, Jaccard and unweighted UniFrac in the NFBC1966 and for the four measures in TwinsUK (Table S2). In the NFBC1966, after inclusion of HOMA-IR in the models, the associations between BMI and microbial composition for binomial and unweighted UniFrac metrics were no longer statistically significant. In the TwinsUK cohort,

BMI remained strongly associated with four beta diversity matrices, regardless of the inclusion of HOMA-IR or CRP in the model (Table S2).

In GAMLSS models adjusted for BMI, gender and smoking status, sixteen individual genera met FDR-adjusted statistical significance with HOMA-IR, ten with CRP and nine with HbA1c in the NFBC1966. Higher values of HOMA-IR were strongly associated with higher average relative abundances of members from the Peptococcaceae (Estimate=11.62, P-value<0.001), Bifidobacteriaceae (genus *Gardnerella*) (Estimate=2.64, P-value<0.001), Veillonellaceae, Lachnospiraceae (genus *Blautia*) and Paraprevotellaceae families and lower average relative abundances of members from the Peptostreptococcaceae (Estimate=-0.52, P-value<0.001), Peptococcaceae (Estimate=-0.23, P-value<0.001), and Prevotellaceae families (Table S3a). Increased CRP was associated with lower average relative abundances of members from the Paraprevotellaceae, Peptococcaceae, Veillonellaceae and Peptostreptococcaceae families and higher average relative abundance of one ASVs, *Peptococcus* (Table S3b). Higher levels of HbA_{1c} were associated with lower average relative abundances of members from the Bifidobacteriaceae, Peptococcaceae, Veillonellaceae and Peptostreptococcaceae families and higher average relative abundance of one ASVs, *Oxalobacter* (Table S3c). For the presence/absence of taxa, the zero models accounting for excess zeros showed that the metabolic biomarkers-taxa associations were never significant except for the genus *Gardnerella* and HbA1c (Estimate=3.87, P-value=0.013).

Although the NFBC1966 results presented in this paper include both men and women, sensitivity analyses were run including women only (n=319) with similar results (data not shown).

Discussion

In this analysis of gut microbiome profiles and metabolic parameters in two population-based cohorts, as levels of HOMA-IR, CRP and HbA1c increased, we observed decreasing richness and/or evenness of the gut microbial taxa, even after adjustment for BMI. In addition, HOMA-IR, CRP and HbA1c were associated with microbial community as indicated by significant associations with three beta-diversity measures, but were not associated with weighted UniFrac, suggesting that there were differences

in community composition when ignoring phylogenetic similarity, but when this was accounted for, the communities were quite similar. Further, HOMA-IR, CRP and HbA1c were significantly associated with the relative abundance of specific taxa, including members of the Peptococcaceae, Bifidobacteriaceae and Veillonellaceae families, but not with their presence or absence. In the NFBC1966, we observed that when including HOMA-IR or CRP in the models, the association between BMI and some measures of alpha- and beta-diversity lost statistical significance. These findings support a potential relationship between insulin resistance and markers of metabolic health and gut microbial diversity that may be independent of BMI.

Our data support the hypothesis that greater gut microbiome diversity is associated with better insulin sensitivity (107). A clinical trial studying the effect of fecal transplant from lean donors to men diagnosed with metabolic syndrome found that insulin sensitivity had improved and gut bacterial diversity had increased 6 weeks post transplantation (209). These results corroborate other studies identifying gut microbial alterations and attenuation of metabolic syndrome after various weight-loss interventions (210,211). Perturbation of homeostatic interactions between the gut microbiome and the host might promote metabolic disturbances but the mechanisms underlying this relationship are not well understood (212) (Figure 1). As described previously, the gut microbiome can trigger inflammatory processes associated with obesity and insulin resistance by stimulating immune cells through lipopolysaccharides derived from bacterial membranes (213,214). Furthermore, microbial-derived short-chain fatty acids, including butyrate (215), can enhance insulin sensitivity (216) and suppress insulin-mediated fat accumulation (217). CRP is a marker of chronic low-grade systemic inflammation associated with obesity and insulin resistance (218). Previous studies have found a relationship between systematic inflammation, through high-sensitivity CRP plasma levels, and microbial composition, supporting our findings (219). Our results suggest that higher levels of HbA1c were associated with a decreased bacterial diversity. Results from the literature seem less clear regarding the association between HbA1c level and gut microbiome composition. Some articles reported evidence of an association between HbA1c level and bacterial group counts (220) while others did not find any significant relationship (221). These findings could be explained by the fact that elevated insulin levels or HOMA-IR appeared to identify

certain traits of metabolic syndrome changes, especially abdominal obesity, earlier than both HbA1c and measures of glucose (222).

Consistent with other studies, BMI was inversely associated with gut microbiome diversity (193). However, following adjustment for HOMA-IR and CRP, this association lost statistical significance with some measures of alpha- and beta-diversity, suggesting that the observed relationship between BMI and gut microbiome diversity might be indirect and influenced by measures of insulin resistance and inflammation. This hypothesis needs to be further explored in other cohorts as results from TwinsUK suggested that associations between BMI and gut microbial diversity were attenuated but remained strongly significant.

Sixteen individual taxa met FDR-adjusted statistical significance with HOMA-IR, ten with CRP and nine with HbA1c. In particular, higher HOMA-IR was associated with higher average relative abundances of members from the Peptococcaceae, Bifidobacteriaceae (genus *Gardnerella*) and Veillonellaceae families while higher CRP levels were associated with lower relative abundances of Paraprevotellaceae, Peptococcaceae and Peptostreptococcaceae. Higher levels of HbA1c were associated with higher presence of the family Bifidobacteriaceae (genus *Gardnerella*). In a previous study, Schott et al. found that the relative abundance of certain pro-inflammatory bacteria, including members from the Peptococcaceae (*rc4-4 sp* genus) and Peptostreptococcaceae, was higher in obese mice (223). Our findings support an association between HOMA-IR and Peptococcaceae *rc4-4 sp* but also show differences in CRP-taxa associations. Insulin-resistant individuals had a significantly higher abundance of Veillonellaceae, which support our findings (224). Relative abundance of succinate-producing Veillonellaceae was also found to be higher in obese individuals (225). No previous studies were found reporting the positive association between HOMA-IR and *Gardnerella* or the inverse association between HbA1c and *Gardnerella* which were found in our study (Tables S1a and S1c). Overall, the GAMLSS models showed that metabolic biomarkers were more associated with the relative abundance of the taxa rather than their presence or absence.

A limitation of our study was the cross-sectional nature of the analyses. Repeated, prospectively collected samples would be needed to study the causal relationships

between gut microbiome and markers of metabolic health and to assess their respective association with risk of diseases such as T2D or cancer. Other limitations of the current study were that TwinsUK was only females, even if sensitivity analyses including females only in the NFBC1966 showed similar results, and that data on HbA1c were not available for the replication. Differences between NFBC1966 and TwinsUK populations have provided interesting insight to explore the association between microbiome and metabolic health. Indeed, a previous study has shown that associations between the microbiome and various risk factors varied by geographic location, it is a potential limitation that some associations may differ in other populations (226). Therefore, being able to see associations between gut microbiome composition and measures of metabolic health in two different populations showed consistency, independently of other potential factors. Finally, we recognize the limited taxonomic resolution and accuracy of the 16S rRNA gene sequencing methodology, preventing us to adequately perform species-level associative analysis and to unambiguously discriminate low-abundance taxa from noise and further replication and extension (e.g., metagenomics) of results in other population-based studies is warranted.

Our study suggests that general population cohorts are valuable in identifying potential associations between microbial features and measures of metabolic health, particularly with low contrasts in exposure and disease. However, the use of cross-sectional data does not allow us to causally interpret these associations, since interactions between metabolic biomarkers and the gut microbiome are complex and dynamic, and can be strongly affected by behavioural changes. Therefore, it is now critical for future studies to collect longitudinal data of both lifestyle exposures and the microbiome to help understand the dynamic relationship between the gut microbiome and host metabolism. Integration of microbiome data paired with fecal metabolomics data will provide a more complete picture of the metabolomics-microbial mechanisms that contribute to metabolic balance between the host and the gut microbiome.

In conclusion, insulin resistance, poor control of blood glucose levels and systemic inflammation were associated with statistically significantly lower gut microbiome diversity and distinct microbial community structures in both the NFBC1966 and TwinsUK, even after control for BMI and other parameters. These results from two

distinct population-based cohorts provide evidence that individuals with worse metabolic control have lower gut microbial diversity and may provide insight into the pathophysiological mechanisms that underlie poor metabolic health. It is, however, impossible to conclude if these differences in microbial composition and taxa associations are a cause or a consequence of metabolic dysfunction. Thus, large-scale, prospective studies with collection of fecal samples and longitudinal data on lifestyle and metabolic biomarkers at several time-points are now needed to validate and extend these observations.

Figure

Figure 1 - Schematic depicting possible interactions between the gut microbiome and host metabolic components

LPS: Lipopolysaccharides; CRP: C-reactive protein; SCFAs: Short-chain fatty acid (including butyrate); HbA1c: Glycated haemoglobin

The gut microbiome might trigger inflammatory processes associated with obesity and insulin resistance by stimulating immune cells through LPS derived from bacterial membranes. In addition, systematic inflammation, through CRP plasma levels, was associated with lower microbial diversity. Microbial-derived SCFAs, including butyrate, may enhance insulin sensitivity and suppress insulin-mediated fat accumulation. The level of HbA1c was inversely associated with gut microbiome composition, however the mechanisms underlying this relationship are not well understood. The association between the gut microbiome and metabolic health parameters is likely complicated by the fact that the relationship between each component could be bidirectional or even cyclical.

Chapter IV: Comparison of fecal sample collection methods for microbial analysis embedded within colorectal cancer screening programs

1. Background

Population-based studies with gut microbiome data collected prior to chronic disease onset are extremely limited. Colorectal cancer screening programs, which provide screening through fecal tests such as the fecal immunochemical test (FIT) and fecal occult blood test (FOBT), may provide a platform for establishing cohorts with repeated, prospectively collected fecal specimens.

2. Objective

The aim of this study was to compare the impact of different fecal collection methods currently used in ongoing colorectal cancer screening programs on microbiome technical reproducibility, accuracy and stability.

3. Methods

Fecal sample processing

Fecal samples from nineteen healthy volunteers were aliquoted across seven different collection methods, including two cryotubes with no solution (considered to be the putative gold standard), two GenSaver specimen collection cards (Ahlstrom-Munksjö, Helsinki, Finland) used in Afghanistan, two GenCollect specimen collection cards (Ahlstrom-Munksjö, Helsinki, Finland) used in Afghanistan, four OC-Auto Sampling tubes (Eiken Chemical, Tokyo, Japan) used in France (and most other European countries), two Hemotrust tubes (Biosynex, Illkirch-Graffenstaden, France) used in Morocco, two One-Step FOB tubes (Padyabteb, Tehran, Iran) used in Iran, and two Specimen Collection Container A tubes (Alfresa Pharma, Osaka, Japan) used in Turkey. Aliquots were then directly frozen at -80°C , or stored at room temperature, 4°C or 30°C , or mailed to undergo colorectal cancer screening procedures before being frozen. Bacterial loads were calculated based on qPCR and microbiome composition were analysed for a total of 304 samples using 16S rRNA gene sequencing.

Statistical analysis

Intraclass correlation coefficients (ICCs) were calculated using the variance components from a one-way ANOVA to evaluate the stability and accuracy of the different fecal collection methods. The ICCs were computed based on (i) the square root of the relative abundances of the three most dominant phyla (Actinobacteria, Bacteroidetes, and Firmicutes) and the most abundant genera (*Faecalibacterium*, *Bacteroides*, *UCG-002*, *Subdoligranulum*, *Roseburia*, *Eubacterium eligens* group, *Blautia*, *Christensenellaceae R-7* group, *Ruminococcus*), which were present in at least 50% of fecal samples with relative abundance of $\geq 0.1\%$, (ii) our three alpha diversity metrics, and (iii) the first multidimensional scaling axis, also called first principal coordinate (PC1), of our four beta diversity metrics. To calculate accuracy ICCs, we compared one replicate of samples without solution frozen immediately (considered as the gold standard), selected randomly, to one sample from each of the other collection methods for each participant. To calculate stability ICCs at different temperatures and procedures for each fecal collection method, we compared one sample frozen immediately to one stored at different conditions for each participant.

4. Results

Variability in diversity was largely explained by differences between participants and less by the collection method. Accuracy and stability ICCs were generally very high for PC1 of beta diversity matrices, except for OC-Auto Sampling tubes stored at 30°C and for Hemotrust tubes stored at room temperatures. Accuracy measures were very inconsistent for the relative abundance of the three phyla and alpha diversity, and in particular, very low for the inverse Simpson. At the genus level, we did not observe any differences in accuracy compared to the putative gold standard between Gram positive or Gram negative bacteria. Genera that represent a phylogenetically narrow group of species, *UGC-002* and *Christenellaceae RT7* group (≥ 0.75). Microbial profile stability was very high for specimen collection cards and seemed generally acceptable for FIT tubes (≥ 0.75), except for Hemotrust tubes (range, 0.06-0.94). Colorectal cancer screening tests did not impact microbiome stability in FIT tubes (≥ 0.75), however, exposure to summer temperatures (i.e. $>30^\circ\text{C}$) (range, 0.41-0.90) did influence stability.

5. Conclusion

Our study supports previous findings indicating that microbial data obtained from FIT tubes and specimen collection cards are relatively stable and accurate and may be appropriate methods to collect fecal samples for gut microbiome analysis in population-based cohort studies. Furthermore, our findings suggest that opportunistic collection of fecal samples in FIT tubes after colorectal cancer screening is feasible, thereby permitting the potential establishment of cohorts within such screening programs.

Key words: colorectal cancer, screening programs, microbiome, fecal sample collection

Abstract

Colorectal cancer screening programs with collection of fecal samples may provide a platform for population-based gut microbiome-disease research. We investigated the impact of fecal sample collection and storage method on the accuracy and stability of 16S rRNA and bacterial load data across seven different collection methods (i.e. no solution, two different specimen collection cards and four types of fecal immunochemical test (FIT) used in four different countries) among 19 healthy volunteers. Intraclass correlation coefficients (ICCs) were calculated for the relative abundance of the top three phyla, the most abundant genera, alpha diversity metrics and the first principal coordinates of the beta diversity matrices to estimate stability of fecal microbial profiles after storage for 7 days at room temperature, 4°C, 30°C and after screening for the presence of occult blood in the stool, and accuracy compared to samples frozen immediately with no solution (i.e. the putative gold standard). When compared to the putative gold standard, significant variation was observed for all collection methods, however, inter-individual variability was much higher than the variability introduced by the collection method. Stability ICCs were high (≥ 0.75) for FIT tubes that underwent colorectal cancer screening procedures, except for the relative abundance of Actinobacteria (0.65), and were lower for different FIT tubes stored at 30°C (range, 0.41-0.90) and at room temperature (range, 0.06-0.94). Our findings indicate that the use specimen collection cards and different types of FIT are acceptable tools for fecal sample collection methods and inform on their utility for developing microbiome-focused cohorts nested within screening programs.

Importance

Population-based studies with prediagnostic collection of fecal samples are lacking and are necessary for providing robust evidence on the role of the gut microbiome in disease development. Our study indicates that microbial profiles obtained from FIT and specimen collection cards are appropriate methods to collect fecal samples for gut microbiome analysis in population-based cohort studies. Furthermore, our findings suggest that opportunistic collection of fecal samples in FIT tubes after colorectal cancer screening is feasible, thereby permitting the potential establishment of cohorts within such screening programs.

Introduction

Evidence on the role of the human microbiome (i.e. the collection of microbes and microbial genes found in the human body) in the development of chronic diseases such as obesity, diabetes and, potentially cancer, is growing (108,227,228). However, most of the current literature on the association of the microbiome with chronic diseases is based on cross-sectional studies that used diverse methods (229). Most established prospective cohorts did not collect fecal samples and repeated, prospectively collected samples are likely necessary for advancing understanding of the relationship between the microbiome and chronic disease development. Colorectal cancer screening programs, which provide screening through fecal tests such as the fecal immunochemical test (FIT), may offer great potential for establishing population-based cohort studies with multiple fecal specimens and epidemiologic data.

The impact of fecal sample collection methods on gut microbiome parameters has been recently investigated (194,230–234). Microbial populations in fecal samples collected using fecal occult blood tests (FOBT) and FIT have been found to be stable at room temperatures for up to 4 to 7 days, with similar microbial communities compared to samples collected without an additive and frozen immediately. For example, in one study conducted among 52 healthy volunteers in the United States, all fecal sample collection methods (i.e. no additive, 95% ethanol, RNAlater, post-development FOBT cards, and FIT tubes) yielded microbial data that appeared relatively reproducible, stable, and accurate, when compared to the putative gold standard, and provided evidence that these collection methods can be employed for microbiome analyses in population-based studies (194).

However, to potentially inform on the establishment of international studies based in colorectal cancer screening programs, additional methodologic work is needed to test FIT and specimen collection cards used in other countries where different FIT methods and screening procedures are employed. Therefore, we designed a study to evaluate microbial stability in fecal specimens stored at room temperatures and accuracy of microbiome metrics from two different specimen collection cards and four different FIT tubes used in ongoing international colorectal cancer screening programs (in France and most European countries, Morocco, Turkey and Iran). Additionally, we investigated the impact of colorectal cancer screening procedures and alternative shipping

temperatures (e.g., summer and winter temperatures) on microbiome accuracy and stability ascertained from FIT samples.

Results

Microbial alpha diversity by collection method - The Shannon index and inverse Simpson index values were, on average, highest for the immediately frozen samples without solution, (i.e. the putative gold standard) and the number of observed OTUs appeared highest in the specimen collection cards (Figure 1). However, the different storage conditions did not seem to have a statistically significant impact on these alpha diversity metrics. From the linear mixed-effects model, we found that compared to the immediately frozen samples without solution (296, 95% CI [257; 335]), the observed number of OTUs was significantly higher in GenSaver cards at room temperatures (347, 95% CI [308; 387], $P = 0.01$) and in OC-Auto Sampling FIT tubes at -80°C (344, 95% CI [305; 383], $P = 0.03$). Compared to the defined gold standard (4.03, 95% CI [3.81; 4.24]), the Shannon index was significantly lower in OC-Auto Sampling FIT tubes at -80°C (3.73, 95% CI [3.51; 3.94], $P = 0.005$), One-Step FOB tubes at -80°C and at room temperatures (3.76, 95% CI [3.54; 3.98], $P=0.03$ and 3.49, 95% CI [3.27; 3.72], $P < 0.001$, respectively), and in Specimen Collection Container A tubes at -80°C and at room temperatures (3.60, 95% CI [3.38, 3.82], $P < 0.001$ and 3.70, 95% CI [3.48; 3.91], $P < 0.001$, respectively).

Percent variability explained by participant and collection method - All multidimensional scaling ordinations suggested that the between participant variability was higher than the technical variability (Figure S2 in supplementary material). In multidimensional scaling (MDS) plots, each point represents one microbiome sample for 19 participants and seven collection methods; all samples from a given participant tended to group together (as shown by ellipses, one per participant). Additionally, based on four distance matrices (i.e. Jaccard, Bray-Curtis, unweighted UniFrac and weighted UniFrac), the overall variability in diversity was largely explained by between participants (55% to 79%) and only marginally by collection methods (4.8% to 14.8%, Figure S3). For example, based on the Bray-Curtis distance matrix, the protocol variability accounted for roughly 6.9% of the overall variability whereas the biological variability accounted for 79.0%.

Relative abundance comparisons - At the phylum level, the distributions of relative abundances of each phylum were consistent for all the collection methods; samples were mainly represented by Firmicutes followed by Bacteroidetes (Figure 2). At the genus level, when compared to the putative gold standard, the relative abundance of *Faecalibacterium* was greater in the other collection methods, especially in the OC-Auto Sampling FIT tubes. Consequently, when compared to gold standard, the relative abundance of other genera, such as *Bacteroidetes* or *Blautia*, was lower in other collections methods. However, there was also substantial inter-individual variability at the genus level (Figure S4 in supplementary material).

Accuracy compared with putative gold standard – Samples collected without solution and immediately frozen at -80°C were considered as the putative gold standard and compared to samples collected using other methods in different storage conditions using ICCs (Figure 3, and Table S4 in supplementary material). Accuracy ICCs were variable for the relative abundance of Actinobacteria (range, 0.28–0.83), Bacteroidetes (range, 0.24–0.84), Firmicutes (range, 0.26–0.82) as well as for the inverse Simpson index (range, 0.23–0.73) and the weighted UniFrac (range, 0.46–0.93). Specifically, for the relative abundance of Actinobacteria, ICCs were $\geq 75\%$ for OC-Auto Samples tubes stored at 30°C and those that went through screening, for One Step FOB tubes stored at room temperatures and for all the specimen collection cards. For the relative abundance of Bacteroidetes, ICCs were $\geq 75\%$ for OC-Auto Samples tubes that went through screening, for One Step FOB tubes immediately frozen and for Specimen Collection Container A tubes immediately frozen. For the relative abundance of Firmicutes, ICCs were $\geq 75\%$ for One Step FOB tubes immediately frozen and for Specimen Collection Container A tubes immediately frozen. ICCs were $\geq 75\%$ for PC1 scores of weighted UniFrac for all the methods, except for OC-Auto Samples tubes stored at 30°C and for Hemotrast tubes stored at room temperatures. At the genus level, we did not detect any links between the accuracy differences and the Gram positive of Gram negative (Figure 4). As expected, genera that represent a phylogenetically narrow group of species, *UGC-002* and *Christenellaceae RT7* group, showed accuracies above 0.75. Conversely, ICCs were higher for observed OTUs (≥ 0.74) except for Hemotrast at room temperatures (0.31), OC-Auto Sampling tubes immediately frozen (0.66) and at 30°C (0.40), and One-Step FOB at room temperatures (0.60). Specimen collection cards showed the highest ICCs

for the Shannon index (range, 0.79–0.88). ICCs were $\geq 75\%$ for PC1 scores of Jaccard, Bray-Curtis and unweighted UniFrac distances for all collection methods. Additionally, technical variability was also quantified based on beta diversity distances between the two replicates of the putative gold standard and used as baseline to assess the accuracy of each method. For each participant, the distance between the putative gold standard and each collection method was computed (Figure S5 in supplementary material). All those distances were slightly higher than the baseline, suggesting that the effect the collection methods exceeds the technical variability.

Stability – In each collection method, samples frozen immediately were compared to the samples stored in different conditions using ICCs (Figure 5, and Table S5 in supplementary material). When compared to specimen collection cards frozen directly, collection cards (i.e. GenCollect and GenSaver) kept at room temperatures showed high stability, with ICCs $\geq 89\%$ for all seven metrics. Stability ICCs were generally lower and more variable in samples collected using Hemotrust tubes (range, 0.06-0.94). For One-Step FOB tubes the confidence intervals were wide, indicating high variability in stability at room temperatures. Specimen Collection Container A tubes at room temperatures showed stability ICCs $\geq 75\%$ except for the relative abundance of Actinobacteria (0.58) and Firmicutes (0.66). Stability ICCs were lower and inconsistent for OC-Auto Sampling FIT tubes stored at 30°C (range, 0.41-0.90). However, stability ICCs were higher for OC-Auto Sampling FIT tubes stored at 4°C (≥ 0.75) except for the number of observed OTUs (0.65). Stability ICCs were also high for OC-Auto Sampling FIT tubes that went through colorectal cancer screening procedures, with ICCs $\geq 75\%$, except for the relative abundance of Actinobacteria (0.65). Interestingly, at the genus level, the stability remained very high, especially for Gencollect and Genesaver. It is worth pointing that *Blautia* genus, including the homoacetogen *Blautia hydrogenotrophica*, was significantly lower at room temperature (Figure 2B and Figure 6) In addition, *UGC-002*, but also *Faecalibacterium*, *Roseburia* and *Ruminococcus* were also subjected variations when stored at 30°C.

Discussion

In this study we compared microbiome stability and accuracy across different fecal sample collection methods (i.e. two different specimen collection cards and four different FIT tubes) used in ongoing colorectal cancer screening programs. We found

that the overall variability in diversity was largely explained by differences between participants and less by the collection method. In addition, accuracy and stability ICCs were generally very high for PC1 of beta diversity matrices, except for OC-Auto Sampling tubes stored at 30°C and for Hemotrust tubes stored at room temperatures. Accuracy measures were very inconsistent for the relative abundance of the three phyla and alpha diversity, and in particular, very low for the inverse Simpson. This highlights the importance of using one consistent method for study comparisons. Overall, microbial profile stability was very high for specimen collection cards and seemed generally acceptable for FIT tubes, except for Hemotrust tubes. Colorectal cancer screening tests did not impact microbiome stability in FIT tubes, however, exposure to summer temperatures (i.e. >30°C) did influence stability. These results are informative for the development of future population-based cohorts with fecal sample collection within colorectal cancer screening programs.

As shown in prior studies that have assessed microbiome diversity in human or animal samples, microbial composition and diversity were largely explained by between-participants differences and only marginally by the collection methods (194,233). Fecal specimen collection cards have been previously tested for microbial analysis in other studies and have shown moderate to excellent accuracy compared to the putative gold standard and stability at room temperatures (230,233,235–240). In this study, the specimen collection cards (i.e. GenCollect and GenSaver) stored at room temperatures for 10 weeks showed excellent stability when compared to the immediately frozen cards, although other studies detected lower amounts of DNA among fecal samples from humans and animals collected on FTA cards (Whatman) after several weeks (238,241). Also consistent with previous findings, we found that specimen collection cards tended to differ in bacterial taxa composition and have observed OTUs than when using the putative gold standard (194,235,241), but we did not observe higher Shannon and inverse Simpson. One hypothesis to explain this observation is that the card matrix may increase chemical cell lysis (235); as in our study, Firmicutes, often spore formers, were the most represented phylum in sample collected with specimen collection cards, supporting the hypothesis that cell lysis might be one explanation for these differences. Furthermore, *Blautia* genus, including the homoacetogen *Blautia hydrogenotrophica*, is also adequately represented in the collection cards, despite being highly sensitive to oxygen.

In previous studies, fecal samples stored in FIT tubes have also shown moderate to excellent accuracy compared to the gold standard and stability at room temperatures (234,242,243). However, the different types of FIT tubes in our study did not seem to perform equally. For the specimen cards and some of the FIT tubes, especially OC-Auto Sampling and Hemotrust tubes stored at -80°C, we detected significant differences in the relative abundance of phyla and genera with higher levels of Firmicutes and *Faecalibacterium* genus, including the anti-inflammatory butyrate producing *Faecalibacterium prausnitzii*, when compared to the gold standard, which support observations from a previous study (243). As described previously (237,242), when compared to the gold-standard, FIT tubes showed good to excellent accuracy for beta diversity metrics, however, some FIT tubes, including OC-Auto Sampling, Hemotrust and Specimen Collection Container A tubes, revealed lower accuracy for alpha diversity metrics, especially those stored for 7 days at room temperatures or at 30°C. Previous studies have found that FIT tubes showed good stability at room temperatures (194,234,243).

Regarding stability at room temperature, we found variable results for the different types of FIT tubes. When compared to those directly frozen, Hemotrust tubes stored at room temperature for 7 days showed poor stability for alpha diversity metrics and for One-Step FOB tubes the confidence intervals were wide, indicating high variability in stability at room temperature. In this study, we detected different stabilities at room temperature for *Eubacterium eligens* and *Roseburia*, other butyrate producers from the human gut microbiota. As OC-Auto Sampling tubes seemed to be less stable at 30°C, the collection and shipping of samples during high temperatures might have an impact on gut microbiome composition. These variations in accuracy and mostly in stability between the types of FIT tubes might be due to differences in DNA-stabilizing and anti-microbial properties of the solution (the composition of which remains proprietary for most methods) inside the tubes, impacting the stabilization of DNA, prevention of bacterial growth, and preservation of microbial profiles.

This study has several limitations. First, we included principally female, healthy participants, which might limit the inference of our results to general populations. However, previous studies have found that stability and accuracy for comparison of

samples that were frozen immediately without solution to other fecal sample collection methods were similar between different populations (194,232,234). Second, we used 16S rRNA gene sequencing to characterize the microbial composition, while other profiling methods such as whole-genome shotgun metagenomics are becoming more commonly employed in high-income settings(244). However, 16S rRNA gene sequencing remains the most affordable method to study the gut microbiome diversity, especially in the context of large epidemiologic cohorts. Additionally, in low-to-middle income countries, where sequencing technologies are not always available, these collection methods, and more specifically specimen collection cards, could be used to detect specific biomarker species that have been associated with specific diseases for example *Fusobacterium nucleatum* or *Parviromonas micra* which have been associated with colorectal cancer development(229,245). Finally, as previously described, freezing procedures might have an impact on relative abundance of Gram-positive and Gram-negative bacteria (246,247), and therefore, considering samples without solution frozen immediately as the gold standard method might be suboptimal. However, in the context of large population-based cohorts, immediate DNA extraction after defecation is likely unfeasible, and therefore, standardization of storage protocols is necessary.

Our study included many different collection methods, including two different specimen collection cards and four different FIT tubes, which are currently being used in ongoing colorectal cancer screening programs around the world. The different collection methods tested in this study has allowed us to highlight a number of important considerations for sample collections in large population settings such as acceptability from participants, safety for processing samples, the volume of kit necessary, the storage logistics and cost. For instance, due to the rigidity of the tubes, the solution in OC-Auto Sampling tubes was not easy to sample safely, however the amount of bacterial DNA obtained by qPCR indicated that sufficient material was available in these tubes. Based on qPCR data, the collected volume could be lowered from 500 microliters to 200 microliters to obtain sufficient DNA for several analyses and rendering it unnecessary to extract all of the liquid which might be logistically challenging. Additionally, storage of specimen collection cards is easier and cheaper than tubes, which might help low-to-middle income countries to develop infrastructure for microbiome research. Finally, because of the small size of the kits, the acceptance

is expected to be higher in the general population, compared to the gold standard, where provision of a whole fecal sample could make subjects uncomfortable and reluctant to participate. Furthermore, in this study, stability was assessed over the course of several days to several weeks at room temperature, but also for different conditions directly reflecting settings in colorectal cancer screening (i.e. shipping at different temperatures reflecting seasonal variation, colorectal cancer screening procedures including mailing and occult blood detection test). This is the first study in which the impact of colorectal cancer screening procedures on fecal samples using FIT tubes has been demonstrated. Importantly, OC-Auto Sampling FIT tubes that went through colorectal cancer screening procedures and tests had good stability, opening opportunities for establishing prospective cohorts within screening populations.

In conclusion, our study supports previous findings indicating that microbial data obtained from FIT tubes and specimen collection cards are relatively stable and accurate and may be appropriate methods to collect fecal samples for gut microbiome analysis in population-based cohort studies. Furthermore, our findings suggest that opportunistic collection of fecal samples in FIT tubes after colorectal cancer screening is feasible, thereby permitting the potential establishment of cohorts within such screening programs. Since different collection methods and high temperatures impact the stability and accuracy, it is important for future investigators, in the context of the implementation of large-scale epidemiologic studies, to coordinate their efforts and follow standardized protocols in order to accurately compare the microbiome between sites, groups or countries and be able to pool microbial data.

Methods

Study participants - Nineteen healthy participants from the International Agency for Research on Cancer (IARC) personnel were recruited in Lyon, France. Eligible participants were at least 18 years of age or older, had not taken antibiotics in the past 3 months and were willing to provide a fecal sample. All participants provided informed consent, and the study was approved by the IARC Ethics Committee. On average, participants were 40.2 years old and had a body mass index of 22.7 kg/m². The majority of participants were female (78.9%), had no weight variation in the past six months (73.7%) and reported having a regular bowel movement at least once per day (94.8%) (Table S1 in supplementary material).

Fecal sample collection - At recruitment, participants were provided with a fecal sample collection kit including all materials needed for the fecal sample collection at the workplace or at home along with collection instructions. To collect the fecal sample, participants were asked to provide a fecal sample in the provided fecal collection containers (Sarstedt, Nümbrecht, Germany) by filling the scoop contained in each tube. The participant collected the fecal sample at the workplace (n=9) or at home (n=10) before going to work and returned it to the study coordinator within a few hours after collection. The study coordinator then delivered it to the laboratory for immediate processing. The participants then completed a questionnaire that was used to obtain information on the time and date of sample collection, typical bowel movements and general information.

Following the collection step, the fecal samples were manually homogenized and aliquoted for the different collection methods (Figure S1 in supplementary material). For each participant, fecal samples were aliquoted into two cryotubes without solution (considered to be the putative gold standard, average weight per cryotube 208.1 mg), two GenSaver specimen collection cards (Ahlstrom-Munksjö, Helsinki, Finland) used in Afghanistan, two GenCollect specimen collection cards (Ahlstrom-Munksjö, Helsinki, Finland) used in Afghanistan, four OC-Auto Sampling tubes (Eiken Chemical, Tokyo, Japan) used in France, two Hemotrust tubes (Biosynex, Illkirch-Graffenstaden, France) used in Morocco, two One-Step FOB tubes (Padyabteb, Tehran, Iran) used in Iran, and two Specimen Collection Container A tubes (Alfresa Pharma, Osaka, Japan) used in Turkey. For specimen collection cards, a disposable wooden spatula was used to smear a small portion of the homogenised feces on each window of the specimen collection cards; the flaps on the cards were closed and then each card was placed in a separate biohazard bag with desiccant bags. The FIT tubes were filled following the instructions provided by the different colorectal cancer screening programs. Specifically, the FIT probes were dipped into the homogenised fecal specimen, and returned to the FIT tubes and were then shaken to mix as instructed. All of these steps were performed by the same laboratory technician.

Fecal sample storage - The study samples are outlined in Table 1. After sample collection and processing at IARC, the two cryotubes and one of each sample type

were immediately stored at -80°C . One of the OC-Auto Sampling tubes was placed in a blue mailer for colorectal cancer screening and mailed to the Reference Centre for Epidemiology and Cancer Prevention in Piemonte (CPO Piemonte) laboratory within 24 hours after processing. To mimic mailing during seasonal temperatures in France, one of the OC-Auto Sampling tubes was stored at a winter temperature (4°C) for 7 days in a refrigerator, returned to room temperature for at least 4 hours, and then frozen at -80°C . The remaining OC-Auto Sampling tubes was stored at a summer temperature (30°C) for 7 days in a water bath, returned to room temperature for at least 4 hours, and then frozen at -80°C . The remaining FIT tubes (i.e. Hemotrust, two One-Step FOB and Specimen Collection Container A tubes) were stored for 7 days at room temperature and then frozen at -80°C . The remaining half of the specimen collection cards (i.e. GenCollect and GenSaver cards) remained at room temperature in a closed cupboard from the date of collection until the date of DNA extraction (average 70.2 days).

On arrival at the CPO Piemonte laboratory, the FIT tubes were processed using standard colorectal cancer screening procedures (248). After testing for occult blood, the FIT tubes were immediately closed with parafilm and shipped to the Micalis Institute (INRAE/AgroParisTech) in Jouy-en-Josas, France for 16S rRNA gene profiling. Upon receipt of all the specimens at the same time, the samples were removed from the tube using pliers and a sterile pipette, transferred to a 1.5 mL Eppendorf tube, shaken, and then two 250 μL aliquots were transferred to a sterile tube and frozen at -80°C .

DNA extraction, real-time quantitative PCR and 16SrRNA sequencing - The samples remaining at IARC were shipped on dry ice, except for the specimen collection cards stored at room temperatures, to the Micalis Institute (INRAE/AgroParisTech) in Jouy-en-Josas, France. For each collection method, sampling volumes were collected with different approaches, for optimal recovery, sterility and safety, as described below. For the specimen collection cards, a rectangular section of the filter was cut in the centre of the filter using a sterile scalpel (average concentration per slice 41.5 $\text{ng}/\mu\text{L}$).

The FIT tubes were thawed for 20 minutes on ice, then manually shaken for 15 seconds and finally, 500 μL of fecal solution were collected as follows: Hemotrust tubes

were manually opened, using the bottom red plastic screw, and gently pressed to transfer all of the liquid into a sterile 2 mL screw cap tube; One-Step FOB tubes were manually opened using the top stopper and the liquid poured into a 2 mL sterile screw cap tube; OC-Auto Sampling tubes and Specimen Collection Container A tubes were opened from the top and a long pipette tip was used to collect 4x125 μ L while shaking in between each sampling.

Total DNA was extracted from 500 μ L aliquots or one sliced section of the cards using the PowerFecal DNA Isolation kit (MoBio Laboratories, Carlsbad, CA, United States) according to the manufacturer's protocol with minor modifications consisting of i) decreasing the volume of buffer based on the 500 μ L aliquots taken from the FIT kits or ii) for the GenCollect and GenSaver keeping the paper filters during the first centrifugations and cell lysis. DNA purity and concentrations of FIT tubes and specimen collection cards were estimated using NanoDrop (Thermo Fisher Scientific, Waltham, Massachusetts, USA) measurements. To account for lack of specificity of NanoDrop, qPCR was used to compare biomass and DNA yield differences in all samples. DNA extracts were stored at -20°C before being used for real-time qPCR and 16S rRNA gene V3-V4 PCR amplification.

DNA extracts were used for bacterial biomass quantification by qRT-PCR analysis of the 16S rRNA genes as previously described (249). Total bacterial biomass was quantified by real-time qPCR using specific primers (HAD-1: 5'-TGGCTCAGGACGAACGCTGGCGGC -3' and HAD-2: 5'-CCTACTGCTGCCTCCCGTAGGAGT-3', annealing at 59 °C), Fast SYBR Green MasterMix (Applied Biosystems) and the StepOne Real-Time PCR system (Applied Biosystems, Life Technologies). A standard curve was generated from serial dilutions of a known copy number of the target gene cloned into a plasmid vector. Final dilution of DNA samples for qPCR were 10^{-3} or 10^{-4} -fold depending on the sample. Bacterial biomass was obtained from two distinct qPCR runs for each participant (Tables S2a, S2b, S2c and S2d in supplementary material). A sample of 25ng of DNA underwent PCR amplification of the V3-V4 region of the 16S rRNA gene; DNA from the specimen collection cards and cryotubes were diluted to 1/10 if their concentration exceeded 30 ng/ μ L. Sequencing was performed at the GenoToul INRAE platform (Castanet-Tolosan, France) using Illumina technology with MiSeq kit V2 2 x 250 bp.

Quality control - A 384-well plate was used for sequencing all the samples in one run. The plate contained quality control samples including negative controls after V3-V4 PCR and positive controls from human gut microbiota that had already been sequenced and analyzed. Most samples from each collection method presented sufficient bacterial biomass for the V3-V4 PCR preceding 16S rRNA sequencing. However, differences in bacterial amounts were observed between the collection methods, with lower quantity for Specimen Collection Container A tubes and One-Step FOB tubes (Table S2c in supplementary material). In detail, one subject had a lower amount of material for two of the One-Step FOB tubes, and two subjects for one of the One-Step FOB tubes, preventing to continue with processing for these samples. Three GenCollect and one GenSaver specimen collection cards were first negative for PCR amplification and then positive after a second PCR with 50ng of DNA instead of 25ng. Conversely, for some fit kits samples (stored at room temperature), PCR which were first negative, were positive when 10ng of DNA extract was used, suggesting the presence of PCR inhibitors. Additionally, technical variability was also quantified based on the distance between the two replicate samples without solution frozen immediately. Technical reproducibility was high, with ICCs $\geq 89\%$ between replicates of the gold standards for all seven tested metrics.

Bioinformatics - Data were stored on secured servers at INRAE MAIAGE (Jouy-en-Josas, France) and IARC (Lyon, France). Sequencing data were analyzed with Find, Rapidly, Otus with Galaxy Solution (FROGS) v3.1.0 (250). Briefly, this pipeline included a pre-processing step where reads were merged with Paired-end read merger (PEAR) (251), dereplicated, and filtered according to their length, mismatches in primers with cutadapt (252), and N content. This step was followed by Swarm clustering (253) with an agglomeration distance of $d = 3$. Chimera detection was then performed using VSEARCH (254) before applying an OTU abundance filter (OTUs $< 0.005\%$ of the total abundance are discarded). The most abundant sequence of each OTU was then affiliated with 100% similarity with blastn against the Silva v138 database (255). Two samples were discarded because of low sequencing depth and all remaining samples were rarefied to 7,144 reads per sample using R package phyloseq. Diversity metrics were then computed to represent the diversity of OTUs in each sample (alpha diversities: Shannon index, number of observed OTUs and Inverse

Simpson index) and the differences between samples (beta diversities: Jaccard, Bray-Curtis, weighted and unweighted UniFrac distances).

Statistical analysis – Statistical analyses were conducted using R, version 3.6.2 and the packages DESeq2, icc, phyloseq and vegan (202,256–258). Descriptive characteristics of study participants were based on the questionnaire provided by the participants. We performed visualization using multidimensional scaling (MDS) plots and all samples from a given participant tended to group together. To assess the impact of the protocol on the alpha diversity, comparison of measures of alpha diversity between each fecal collection method was performed and a linear mixed-effects models with the collection method as fixed effect and the participant as random effect was fitted to the data and used to calculate least-squares means of the alpha diversity metrics. Mean diversities for the collection methods were then compared using Tukey's HSD tests. To estimate a distance-based coefficient of determination (R^2) explained by participant and collection method from unweighted UniFrac, weighted UniFrac, Jaccard and Bray-Curtis distance matrices, permutational multivariate analysis of variance was performed (adonis() function, vegan package, R) (202). We calculated intraclass correlation coefficients (ICCs) using the variance components from a one-way ANOVA to evaluate the stability and accuracy of the different fecal collection methods. The ICCs were calculated based on (i) the square root of the relative abundances of the three most dominant phyla (Actinobacteria, Bacteroidetes, and Firmicutes) and the most abundant genera (*Faecalibacterium*, *Bacteroides*, *UCG-002*, *Subdoligranulum*, *Roseburia*, *Eubacterium eligens* group, *Blautia*, *Christensenellaceae R-7* group, *Ruminococcus*), which were present in at least 50% of fecal samples with relative abundance of $\geq 0.1\%$, (ii) our three alpha diversity metrics, and (iii) the first multidimensional scaling axis, also called first principal coordinate (PC1), of our four beta diversity metrics. The first axis explained 8.2%, 15.8%, 17.6%, and 49.7% of the variability for Jaccard, Bray-Curtis, unweighted UniFrac and weighted UniFrac distances, respectively. To calculate accuracy ICCs, we compared one replicate of samples without solution frozen immediately (considered as the gold standard), selected randomly, to one sample from each of the other collection methods for each participant. To calculate stability ICCs at different temperatures and procedures for each fecal collection method, we compared one sample frozen immediately to one stored at different conditions for each participant. The 95%

confidence interval was estimated using the ICCest() function from the R ICC package with default option confidence interval = “Smith”.

Tables

Table 1 - Collection methods for fecal samples and number of aliquots used for microbiome analyses per participants, IARC, Lyon, France, 2019.

| Collection Method | Frozen immediately | 4°C for 7 days | 30°C for 7 days | Room temperature for 7 days | Room temperature for study duration | Mailed to CPO Piemonte, Italy |
|---------------------------------------|---------------------------|-----------------------|------------------------|------------------------------------|--|--------------------------------------|
| No solution | 2 | 0 | 0 | 0 | 0 | 0 |
| GenSaver cards | 1 | 0 | 0 | 0 | 1 | 0 |
| GenCollect cards | 1 | 0 | 0 | 0 | 1 | 0 |
| OC-Auto Sampling tubes | 1 | 1 | 1 | 0 | 0 | 1 |
| Hemotrust tubes | 1 | 0 | 0 | 1 | 0 | 0 |
| One-Step FOB tubes | 1 | 0 | 0 | 1 | 0 | 0 |
| Specimen Collection Container A tubes | 1 | 0 | 0 | 1 | 0 | 0 |

Figures

Figure 1 Impact of specimen collection methods on microbial alpha diversity indexes.

Box represent the median and interquartile range for observed OTUs (A), Shannon index (B) and inverse Simpson index (C) by specimen collection method.

Figure 2 - Variability of microbial phyla and prevalent genera obtained from the collection methods.

Bars represent the relative abundance of bacterial phylum (A) and genus (B) present in at least 50% of fecal samples with relative abundance of $\geq 0.1\%$ in each collection methods.

Figure 3 - The accuracy of phylum distribution and diversity metrics accuracy differ upon the collection method.

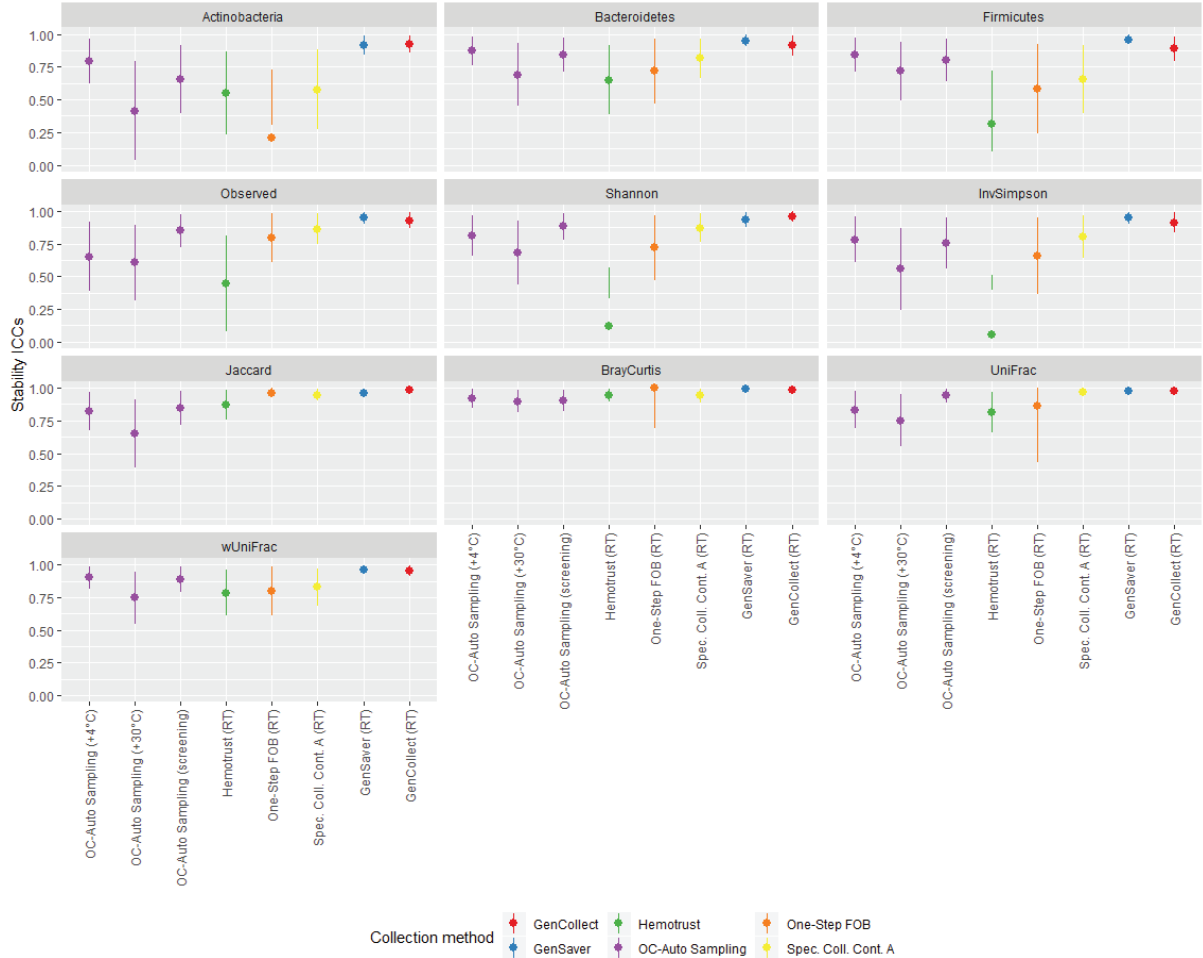

ICCs for accuracy of microbiome diversity metrics are represented of each fecal sample collection method compared to the gold-standard (samples with no solution, frozen immediately).

Figure 4 - The accuracy of genera distribution differ upon the collection method.

ICCs for accuracy of the relative abundance of bacteria at the genus level are represented of each fecal sample collection method compared to the gold-standard (samples with no solution, frozen immediately).

Figure 5 – Impact of storage conditions on the microbiota composition and diversity indexes.

ICCs for stability of microbiome diversity metrics of each fecal sample collection method stored in different conditions compared to those directly frozen.

Figure 6 – Impact of storage conditions on the most abundant genera.

ICCs for stability of the most abundant bacteria at the genus level of each fecal sample collection method stored in different conditions compared to those directly frozen.

Supplementary material

Figures

Figure S1 - Pictures of the different collection methods: (A) OC-Auto Sampling tubes, (B) Hemotrust tubes, (C) Specimen Collection Container A tubes, (D) One-Step FOB tubes, (E) GenSaver and GenCollect specimen collection cards.

Figure S2 – Multidimensional scaling (MDS) plots for microbiome feature data types. In multidimensional scaling (MDS) plots, each point represents one microbiome sample for 19 participants and seven collection methods. Four distance matrices were considered: Jaccard (A), Bray-Curtis (B), unweighted UniFrac (C) and weighted UniFrac (D). All samples from a given participant tended to group together (as shown by ellipses, one per participant). The “gold standard”, or reference methods (two samples without solution, directly frozen), were highlighted by bigger points and most points that were far from their reference correspond to storages at room temperature or high degree (+30°C).

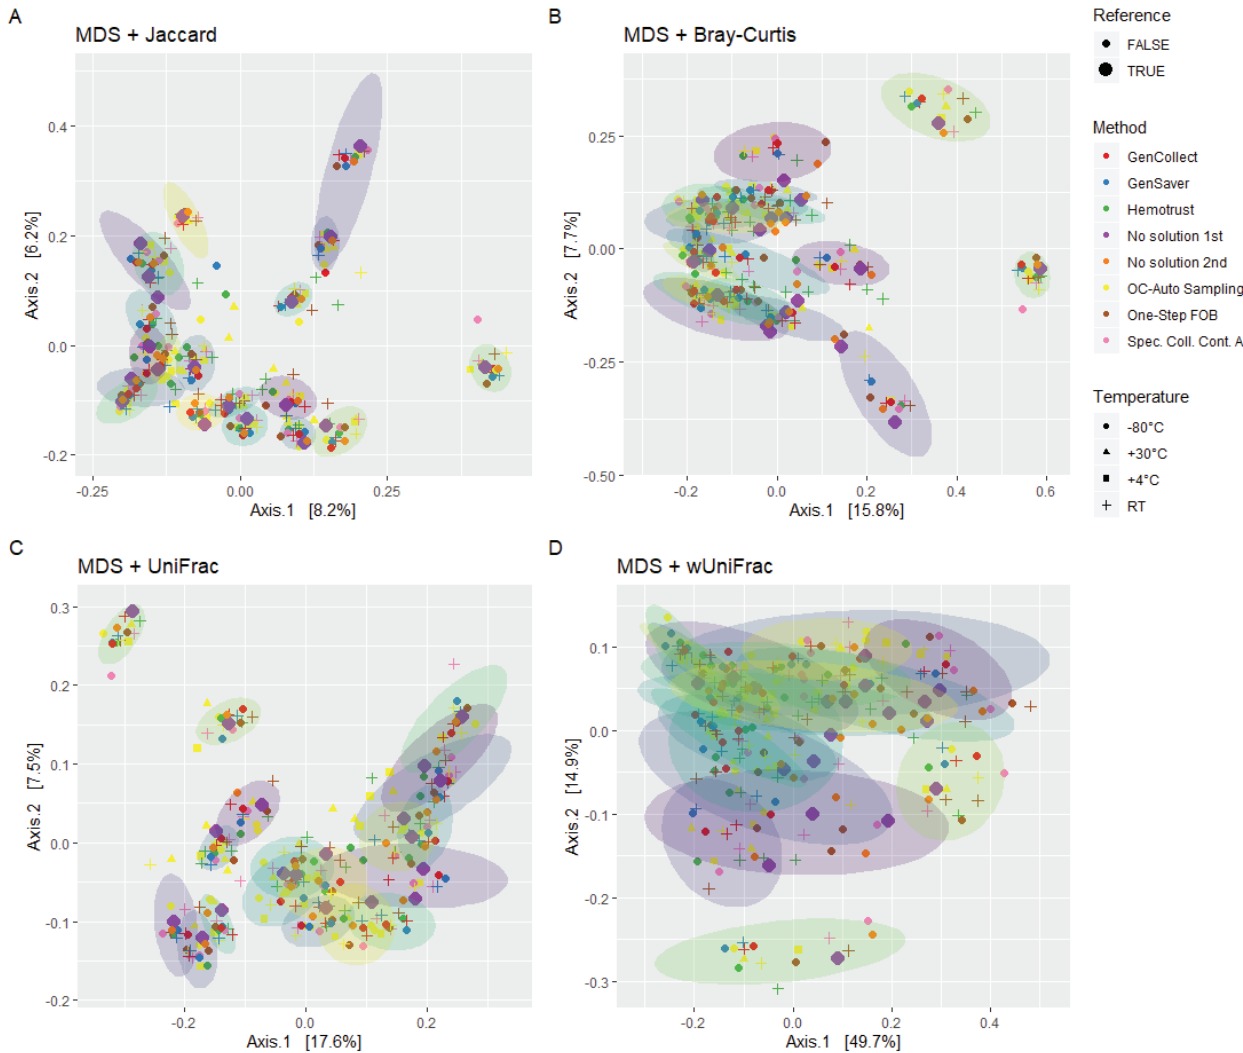

Figure S3 – Percent variability explained by individuals and collection methods using a distance-based coefficient of determination (R^2) for four beta diversity estimates. Based on Bray-Curtis, Jaccard, weighted and unweighted UniFrac distance matrices, inter-participant variability (individual, grey) explained 79%, 54.7%, 64.1% and 71.3% of variability, respectively; whereas the collection method (protocol, orange) explained 6.9%, 4.8%, 4.7% and 14.8% of variability, respectively.

Figure S4 - Relative abundance of bacterial phylum (A) and genus (B) present in at least 50% of fecal samples with relative abundance of $\geq 0.1\%$ in each collection methods, by participant.

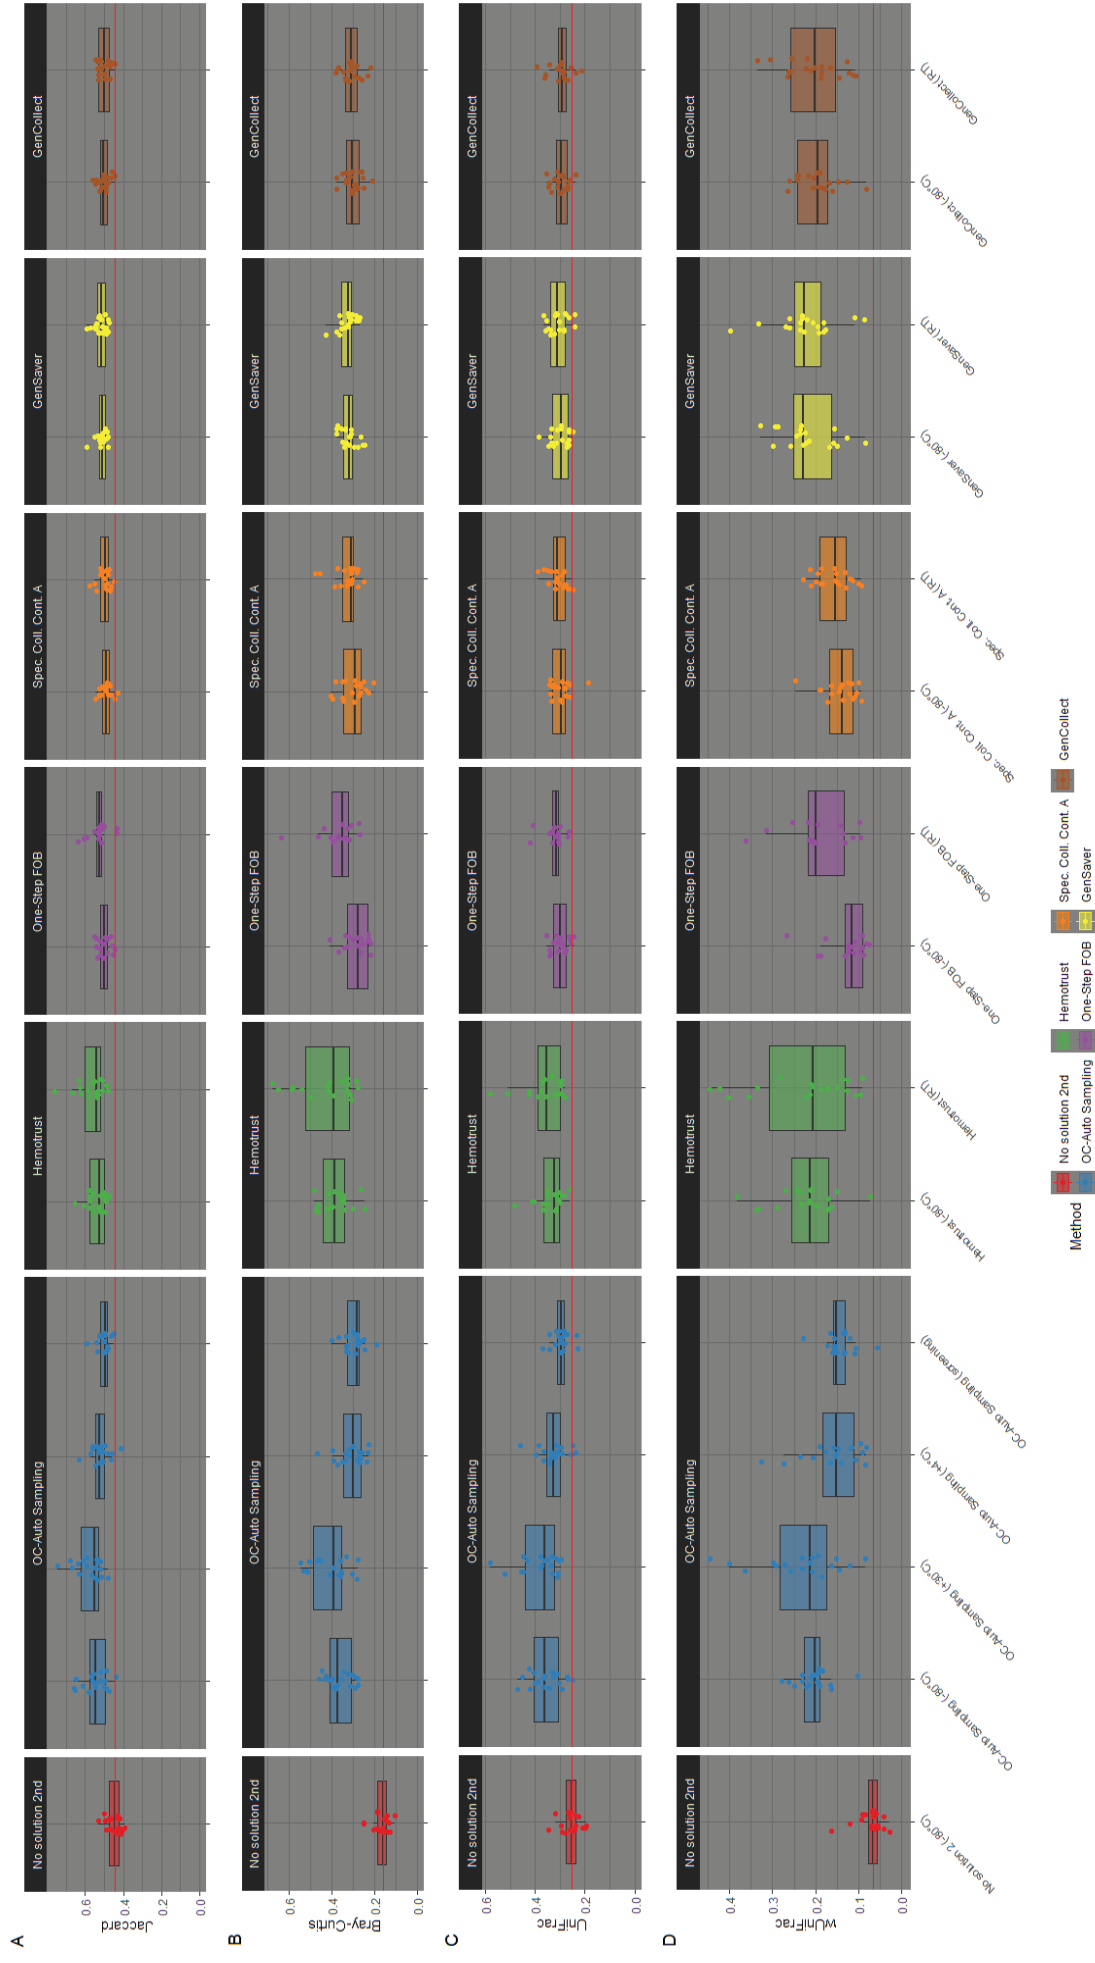

Figure S5 – Distance between the gold standard and each collection method based on Jaccard (A), Bray-Curtis (B), unweighted UniFrac (C) and weighted UniFrac (D) distance matrices. Technical variability was quantified based on the distance between the two replicates of the gold standard and is highlighted by the red line.

Tables

Table S1 – Characteristics of study participants (n=19).

| Characteristic | N (%) | Mean (\pm SD) |
|--|--------------|-----------------------------------|
| Female | 15 (78.9) | |
| Age, years | | 40.2 \pm 8.43 |
| Body Mass Index, kg/m ² | | 22.7 \pm 3.14 |
| No weight variation in the past 6 months | 14 (73.7) | |
| Bowel movement at least once/day | 18 (94.8) | |

Table S2d – Results from qPCR, means for all collection methods.

| Sample name | Bacterial DNA concentration (ng/ μ l) | Sample mass (mg) | Bacterial quantity/g | log(Bacterial quantity/g) | Bacterial quantity/slices | log(Bacterial quantity/slices) | Bacterial quantity/mL | log(Bacterial quantity/mL) |
|--|---|------------------|----------------------|---------------------------|---------------------------|--------------------------------|-----------------------|----------------------------|
| Mean cryotube1 (-80°C) | 87.95 | 284.47 | | | | | | |
| Mean cryotube2 (-80°C) | 62.78 | 131.79 | 9.99E+10 | 10.90 | | | | |
| Mean GenSaver (-80°C) | 43.12 | | | | 4.39E+10 | 10.58 | | |
| Mean GenSaver (RT) | 36.62 | | | | 1.92E+10 | 10.21 | | |
| Mean GenCollect (-80°C) | 48.24 | | | | 4.03E+10 | 10.52 | | |
| Mean GenCollect (RT) | 38.03 | | | | 3.56E+10 | 10.36 | | |
| Mean OC-Auto Sampling (-80°C) | 4.34 | | | | | | 2.34E+09 | 9.21 |
| Mean OC-Auto Sampling (+4°C) | 3.71 | | | | | | 1.77E+09 | 9.06 |
| Mean OC-Auto Sampling (+30°C) | 3.40 | | | | | | 1.56E+09 | 9.11 |
| Mean OC-Auto Sampling (screening) | 3.13 | | | | | | 7.28E+08 | 8.75 |
| Mean Hemotrust (-80°C) | 3.30 | | | | | | 5.37E+09 | 9.66 |
| Mean Hemotrust 19 (RT) | 3.59 | | | | | | 3.48E+09 | 9.37 |
| Mean Specimen Collection Container A (-80°C) | 1.75 | | | | | | 9.09E+08 | 8.83 |
| Mean Specimen Collection Container A (RT) | 1.71 | | | | | | 3.64E+08 | 8.45 |
| Mean One-Step FOB (-80°C) | 1.63 | | | | | | 4.20E+09 | 9.54 |
| Mean One-Step FOB (RT) | -0.23 | | | | | | 2.75E+09 | 9.26 |

Table S3 – Adjusted means for observed OTUs, the Shannon index and the inverse Simpson index by fecal sample collection method.

| Collection method | Observed OTUs | | | Shannon index | | | Inverse Simpson index | | |
|------------------------------|---------------------|--------------|--------------|---------------|--------------|--------------|-----------------------|--------------|--------------|
| | Adj. Mean | Lower 95% CI | Upper 95% CI | Adj. Mean | Lower 95% CI | Upper 95% CI | Adj. Mean | Lower 95% CI | Upper 95% CI |

Chapter V: Discussion and perspectives

In this chapter, the main findings reported in the three result chapters (II to IV) are summarised with regard to the objectives and compared with the broader evidence. In addition, research perspectives are discussed and future recommendations formulated.

1. Discussion

The first part of the thesis aimed to evaluate the strengths and weaknesses of the current evidence on the relationship between the human microbiome and cancer in epidemiological studies (objective I). Among all the anatomical sites evaluated, the gut microbiome followed by the oral microbiome were most frequently studied in human observational studies. The majority of articles reported specific differences in microbiome diversity and/or composition between cases and control groups (including not only non-cancer patients but also tissues). Fifty studies reported significant differences in gut microbiome composition between colorectal cancer patients and various controls. Overall, there was consistent evidence that the abundance of pro-inflammatory opportunistic taxa, such as *Fusobacterium*, *Parvimonas* and *Porphyromonas*, was increased in colorectal cancer patients compared to non-cancer cases while a depletion of butyrate-producing bacteria was observed. Sixteen studies described differences in oral microbiome composition between oral cancer patients and controls. Enrichment of *Fusobacterium* and depletion of *Streptococcus* was reported in patients with oral cancer compared with controls. Interestingly, many bacteria from the oral cavity were not only associated with oral cancer but also with other cancer sites.

With respect to objective I, the discovery of consistent associations for certain taxa of the gut microbiome and colorectal cancer risk, and for the oral microbiome and oral cancer risk, represented a significant advancement in the current evidence on the relationship between the human microbiome and cancer in epidemiological studies. However, this strength was somewhat outweighed by certain methodological barriers and the overall evidence was still too weak to draw firm conclusions. For instance, other differences in the abundance of certain bacteria were found between cancer

cases and controls, but were less consistent between studies. As stated in the introduction of the thesis, these inconsistent findings are likely due to the fact that measurement and analysis of microbiome data are still very limited in the field of cancer epidemiology. Most studies on the relation between the human microbiome and cancer have employed case-control and other cross-sectional designs without repeated measurements. Thus, it remains difficult to establish the causality of the cancer–microbe associations. It is not clear whether the carcinogenic process changes the local micro-environment and creates new niches for bacteria, or if an alteration of microbiome composition and functions contribute to carcinogenesis (129,187). In addition, poor reproducibility between studies and more specifically, variations in study design and methods used to characterise the microbiome can impact the comparability between these different studies (196). Moreover, much is still unknown on microbiome stability and therefore, different sample storage strategies (259,260), laboratory methods, sterilisation procedures, sequencing strategies and various processing pipelines for the raw microbiome sequence data (261) can all impact the comparability of different studies (196,262). Standardised methods for the collection of samples, preparation and handling of samples, and bioinformatics processing of data are now needed (196). Therefore, repeated, prospectively collected samples from population-based cohort studies, using standardised protocols, are necessary for better understanding of the temporal nature of microbial associations with cancer.

The second part of the thesis aimed to investigate the association between insulin resistance and inflammation, established colorectal cancer risk factors, and the gut microbiome using population-based epidemiological data (objective II). To this end, we examined gut bacteria 16S rRNA gene sequence data with serologic levels of homeostatic model for insulin resistance, HbA1c and CRP in two populations of individuals from the Northern Finland Birth Cohort and TwinsUK. Globally, we found that higher levels of these metabolic parameters were associated with decreasing richness or diversity of microbiome composition in the two cohorts. Most importantly, this relationship between high levels of metabolic parameters and lower microbiome diversity remained statistically significant, even after control for body mass index and other health indicators. In addition, in both cohorts, insulin resistance was associated with unweighted UniFrac but not with weighted UniFrac. As seen in table 2 of the introduction, UniFrac is a measure based on phylogenetic measures of community

beta diversity. The unweighted UniFrac measure allows the detection of differences in the presence or absence of lineages of bacteria in different communities (263). On the other hand, weighted UniFrac is a quantitative variant of UniFrac and helps detecting differences in abundance even when the overall groups of organisms that are present in each sample remain the same. In other words, when considering the full microbial community, we found that insulin resistance was associated with differences in the presence or absence of bacteria in different communities but not with differences in abundance. We have also investigated the association between insulin resistance and specific genera using the zero-inflated beta regression model in which, the presence/absence of the taxon in the samples is modelled with a logistic component and the non-zero abundance of the taxon is modelled with a beta component (264). Using these indicators, we found that insulin resistance was associated with the relative abundance of specific genera rather than their presence or absence.

In regard to objective II, the Northern Finland Birth Cohort and TwinsUK data sets are currently quite unique in that fecal samples had been systematically collected and despite their cross-sectional design, by utilising microbiome data obtained from these samples we were able to provide evidence that support previous experimental observations on the link between metabolic health and the gut microbiome. Our findings suggest that there is a relationship between the gut microbiome and metabolic health that is independent of obesity and other measured factors. However, due to the cross-sectional nature of these two studies, it is impossible to conclude from our findings if these differences in microbial composition and taxa associations are a cause or a consequence of metabolic dysfunction. This relationship is likely complicated by the fact that the interactions between the gut microbiome, the host metabolism, the host immune system and potential associated chronic diseases, such as obesity, could be multidirectional or even cyclical. Conclusions from both objective I and objective II indicate that epidemiological findings from cross-sectional population-based studies should encourage the development of prospective studies with longitudinal collections of fecal and blood samples to further interrogate the causal nature of the association between colorectal cancer risk factors and the gut microbiome.

The third part of the thesis aimed to evaluate the impact of fecal sample collection methods used in ongoing colorectal cancer screening programs on the gut microbiota

(objective III). We investigated seven methods of fecal sample collection gathered from nineteen volunteers. These methods included no solution, two different specimen collection cards (recently used by an IARC-based study in Afghanistan), and four types of FIT used in ongoing colorectal cancer screening programs in France (and most other European countries), Morocco, Iran and Turkey. Stability of fecal microbial profiles after storage for 7 days at room temperature, 4°C, 30°C and after screening for the presence of occult blood in the stool, and accuracy compared to samples frozen immediately with no solution were estimated. Reassuringly, the major source of variation of fecal microbial profiles using 16S rRNA gene sequencing was the between individual variability, followed by between collection methods. Overall, accuracy of beta diversity measures was generally very high when compared to samples frozen immediately with no solution. However, these collection methods differed in the relative abundance of various phyla and genera, and alpha diversity measures. In addition, microbial profile stability was very high for specimen collection cards and seemed generally acceptable for FIT tubes, except for Hemotrust tubes stored at room temperature and OC-Auto Sampling tubes stored at 30°C. Most importantly, our findings indicated that passage through colorectal cancer screening tests did not impact microbiome stability in FIT tubes.

With respect to objective III, the evaluation of these fecal sample collection methods used in ongoing colorectal cancer screening programs indicates that opportunistic collection of fecal samples in FIT tubes after colorectal cancer screening is feasible. This supports the hypothesis stated in the introduction that colorectal cancer screening registries in which millions of FIT samples are being collected each year, might provide rich opportunities to establish cohorts of individuals with pre-diagnostic collected fecal samples. Our study was informative on several levels since it showed that most, but not all, fecal sample collection methods were viable for microbiome analysis, and therefore provided information that researchers may wish to consider in planning and executing future prospective studies. The variations in accuracy and mostly in stability between the different types of FIT tubes for the relative abundance of various bacteria highlighted the importance of using at least one consistent method for study comparisons. As seen in objective I, conducting pooled analyses or meta-analyses is not possible if individual studies collect fecal samples using different methods. However, to attain adequate power to detect disease associations with microbiome

profiles, microbiome data will likely have to be pooled across multiple studies. In addition, variations in accuracy and mostly in stability were observed between the different types of FIT tubes. A large variety of FIT tubes from different manufacturers are available on the market, and each FIT buffer might have different DNA-stabilizing and anti-microbial properties. The most commonly employed OC-Auto Sampling FIT seems to be reliable for microbiome analysis, however other types, such as Hemotrust tubes, revealed limitations in terms of stability at room temperature. Moreover, the low microbial profile stability of OC-Auto Sampling tubes stored at 30°C indicated that seasonal variation should be taken into account when collecting fecal samples from colorectal cancer screening programmes. Although opportunistic collection of fecal samples from populations using colorectal cancer screening methodologies is a cost-effective option that might facilitate the inclusion of participants and the collection of repeated specimens, effort should be granted to coordinate protocols across studies for the use of similar types of collection methods.

2. Research perspectives

With respect to the findings of this thesis, future research aiming at improving the understanding of the role of the intestinal microbiota in colorectal cancer development should consider the following challenges and opportunities.

One major limitation identified from the first part of this thesis was that it was not possible to provide quantitative results from meta-analysis due to incomparable results from individual studies. As previously indicated, comparing published data is complicated by lack of standard processing and analysis method. Prior meta-analyses of case-control gut microbiome studies focusing on obesity, inflammatory bowel disease or colorectal cancer have been conducted, however, results were not always consistent (265–268). For example, a meta-analysis from multiple microbiome studies to identify microbial markers associated with colorectal cancer revealed that the ability to detect certain microbiome-colorectal cancer associations was limited due to differences across studies in terms of sample collection, DNA extraction methods and 16S rRNA gene sequencing region as characterised by samples clustering primarily by their original studies rather than colorectal cancer case-control status (268). In addition, these meta-analyses have been limited by focusing on one or two diseases,

and therefore, focusing on a broader landscape of diseases, such as different cancer sites, is even more complicated. Pending the implementation of collaborative microbiome cohorts with global standardisation, the sharing of microbiome data along with metadata should be encouraged to allow members of the scientific community to replicate, confirm and build on individual existing findings (261,262). However, if collecting raw amplicon sequencing data sets could permit systematic re-processing and re-analysis of the data in a way that allows meta-analysis, many other possible sources of variation should still be considered, such as experimental and sequencing artefacts or host confounders (54,56).

Findings from the second part of this thesis revealed an interesting statistical consideration in the analysis and interpretation of microbiome data. As mentioned above, in both the Northern Finland Birth Cohort and TwinsUK, we found that insulin resistance was associated with differences in the presence or absence of bacteria in different communities but not with differences in abundance when using weighted and unweighted UniFrac beta diversity measures. On the other hand, when using a zero-inflated beta regression model, we found that insulin resistance was associated with the relative abundance of specific genera rather than their presence or absence. One explanation could be that the association between insulin resistance and microbiome diversity captured by beta diversity measures was likely driven by a consortium of bacteria present at low relative abundance, as beta diversity matrices take into account the entire microbial community while the zero-inflated beta regression model directly addresses the distribution of single bacteria (269). Another explanation might be that the specific lineages that are driving the association with insulin resistance were excluded from the zero-inflated beta regression model due to very low relative abundance or prevalence since this model directly addresses the distribution of genera relative abundance that resemble a zero-inflated beta distribution (264). Finally, one other explanation could be that beta diversity matrices were computed at the ASVs level and not at the genus level. Microbiome data are high-dimensional structured multivariate sparse data and because of their compositional nature, microbiome data analysis can be challenging (270,271). The Northern Finland Birth Cohort and TwinsUK data could provide opportunities to evaluate current methodologies employed in microbiome statistical analysis and could help to develop new standardised methods for future studies.

In the Northern Finland Birth Cohort analysis, a potentially important finding was that the relationship between higher levels of insulin resistance and lower microbiome diversity was independent of body mass index suggesting that the observed relationship between the body mass index and the gut microbiome diversity might also be influenced by measures of insulin resistance. In addition, although this finding were only observed in the Northern Finland Birth Cohort, the association of body mass index and microbiome diversity was attenuated when adjusting the model for insulin resistance, supporting that some of the body mass index-microbiome relation might be driven through insulin resistance. However, this hypothesis needs to be further explored. One possibility would be to stratify the data by body mass index and verify if the association between insulin resistance and gut microbiome diversity is still observed in lean individuals. However, this analysis would require a larger sample size as only few participants in our study had normal weight with high insulin resistance levels or were obese with low insulin resistance levels. A recent study from Korea evaluated differences in microbiota composition between 317 metabolically healthy and 430 metabolically unhealthy obese individuals (272). Significant differences in gut microbiome composition was observed between the two groups and metabolically unhealthy obese individuals had lower microbial diversity compared to metabolically healthy obese controls. Although these results should be interpreted carefully due to the cross-sectional design of the study and the selection of obese individuals only, these findings support the hypothesis that there is a link between the gut microbiota and metabolic health independent of obesity. Another study, using data from the European Prospective Investigation into Cancer and Nutrition (EPIC) cohort, has shown that metabolic health (characterised by insulin levels) might be a risk factor for colorectal cancer independent of obesity (203). However, the etiology of poor metabolic health in lean phenotype is still unknown and therefore, makes the prevention of associated diseases such as colorectal cancer difficult. One potential explanation could be that alterations of the gut microbiome could interfere with intestinal permeability, increasing the absorption of LPS which initiates activation of Toll-like receptors, inducing increased inflammation and impairment of insulin signalling pathways (273). Understanding the relationship between the gut microbiome and insulin resistance in lean persons could open up new research lines for the prevention of colorectal cancer by targeting the gut microbiome through diet and drugs.

The Northern Finland Birth Cohort represents a valuable platform for future microbiome analysis as many different types of data have been collected. For instance, global biochemical profiles were also measured using a non-targeted metabolomics approach in a subset of fecal samples and have been explored in relation to obesity (204). The availability of both microbiome and metabolomics data will allow us to explore connections between the gut microbiome and fecal metabolome. Such integrated analysis will provide further insight into the likely complex relationship that we observed between gut microbiome profiles and markers of metabolic health. As mentioned in the introduction, 16S rRNA gene sequencing data does not provide sufficient resolution for species-level analyses and therefore, insights into the functional relationships between the gut microbiome and the host remain challenging. The use of metabolomics in the Northern Finland Birth Cohort might help to infer the functional status of host-microbial relationships in fecal specimens (204–206). Indeed, while 16S rRNA gene profiling provides information on gut microbiome composition and diversity, metabolomics could additionally describe microbial activity. We plan to run such microbiome-metabolomics analyses in the Northern Finland Birth Cohort, to better understand the link between metabolic health parameters and the gut microbiome.

In addition to fecal samples, serum samples are also available in the Northern Finland Birth Cohort and as such, potential associations between metabolic profiles in fecal and serum samples could be analysed and compared with gut microbiome composition. Previous studies using mouse models have shown that the accumulated levels of gut microbial metabolites in the intestinal tract does not always correspond with that in the host circulation (207,208). Another extension of our work could consist of parallel analyses of fecal and serum metabolites to help understand the biosynthetic pathways of gut microbial metabolites under different pathophysiological states of the host or identify gut microbiome-derived metabolites.

The observed association of microbiome diversity measures with serologic levels of metabolic health biomarkers in the Northern Finland Birth Cohort may have also been inflated or attenuated by unmeasured or poorly measured confounders, such as dietary intake. Given the diversity of foods in diets, accuracy of dietary exposure is always challenging in free-living populations, and some degree of measurement error is inevitable due to the inaccurate identification of different food components (209,210).

In the Northern Finland Birth Cohort, dietary questionnaire data and fecal metabolomics, along with serum metabolomics, could be analysed to identify metabolites related to specific food components or food patterns and assess associations of these markers with gut microbiome composition and diversity, and metabolic health parameters (211,212). We plan to run this analysis in the next phase of our research.

It is important to place the results from the third part of this thesis in context with cost and feasibility for implementation of fecal sample collection in large-scale studies and use for other –omics analyses. For example, immediately freezing samples with no solution at -80°C is likely to be infeasible in larger population-based studies and, in absence of DNA stabilising agents, their stability when left at room temperature for longer periods of time is questionable (189,213–216). In addition, although considered as the “gold standard”, it is difficult to ascertain whether the results seen with these samples is representative of the actual microbiome composition in the intestinal tract of the host, especially since bacterial growth is possible during freezing/thawing processes or collection conditions (e.g. self-collection at home) (217–219).

On the other hand, antimicrobial agents in the buffer allows DNA stabilisation which confer acceptable microbial stability for FIT tubes stored at room temperature (194,234,242,243), but not at high temperatures. However, FIT tubes also include stabilising solutions which are proprietary and stability may differ by manufacturers, as described in this thesis. In addition, FIT tubes have previously been found to be suboptimal for metabolomics studies, especially when stored at ambient temperature (224). Laboratory practices should also be considered as the implementation in large-scale studies might require automatization of certain processes. For example, we found that due to the rigid plastic frame of certain type of FIT tubes, manual buffer extraction was complicated. Based on qPCR data, our findings indicated that it is unnecessary to extract the complete volume of the solution to obtain sufficient DNA which might be logistically easier in population-based studies. In addition, depending on the manufacturer, FIT tubes are of different sizes and some can be quite large, which could be another challenge to address if thousands of samples need to be stored at -80°C in future population-based studies.

In our study, the specimen collection cards stored at room temperatures for ten weeks showed excellent stability when compared to the immediately frozen cards, as previously described (230,233,235–240). In addition, they also have the advantage to be easily transportable and storable, and cheap, which are important considerations in the context of setting up large-scale population-based studies. Specimen collection cards were also found to be optimal for metabolomics studies, as they were reproducible, stable, and accurate in different studies (233,288).

Further analyses could be conducted to evaluate these collection methods since additional samples frozen immediately at -80°C with no solution are stored at IARC. For example, effects of long-term storage without buffer can be tested as microbiome composition could be investigated over long periods in many future population-based prospective cohorts, and new analyses may be required after several years. The effect of long-term freezing on fecal microbiome stability has previously been investigated for storage at -80°C for more than two years (282) and for storage at -20°C for more than 14 years (289). In these studies, long-term storage seemed to induce few significant changes in microbial community, with few variations in some relative abundances of specific taxa but similar microbiome diversity measurements, confirming stability of the fecal microbiome during long periods of freezing, even for freezing conditions at -20°C . The replication and validation of these results using our samples would be interesting, even if cryopreservation protocols, such as the time and storage conditions until freezing as well as the freezing process itself, should not be ignored (247). In addition, technical reproducibility of our results could also be performed by re-processing the samples frozen immediately at -80°C with no solution in another laboratory, taking account of the potential effect of longer storage conditions. Finally, the demultiplexed 16S rRNA gene sequencing data could also be used to compare the impact of different bioinformatics pipelines and processes on the results. For example, comparison of Swarm (253) with some of the most widely-used denoising methods, such as DADA2 (23) and Deblur (290), could be run on an artificial community to estimate alpha diversity measures and microbial composition and then replicated in our dataset on host-associated communities.

Previous methodological work, in addition to our findings indicating that detection of occult blood in stool samples does not impact microbiome accuracy and stability in FIT

tubes, now serve as a proof-of-concept for the establishment of an international microbiome network that has been initiated by investigators from IARC and the National Cancer Institute (USA), along with researchers with expertise in the microbiome and representatives of colorectal cancer screening programs from different countries. One project from this international consortium that is already ongoing is a study of FIT-collected fecal samples in the colorectal cancer screening program of the Piedmont region in Italy. Gut microbiome profiles will be characterised and compared using shallow shotgun sequencing in screened-individuals who were FIT-positive and diagnosed with colorectal neoplasms, or FIT-positive but colorectal neoplasm-free after colonoscopy, or FIT-negative. Another aspect of this network comprises the implementation of feasibility studies nested within various colorectal cancer screening programs to evaluate the achievability of establishing a large multi-country prospective cohort of individuals with repeated fecal microbiome samples as well as epidemiologic and other clinical data.

3. Conclusion

This thesis has contributed to the investigation of the role of the gut microbiome in colorectal cancer using epidemiological approaches. The systematic review of the current evidence linking the human microbiome with cancer stressed that prospective studies with standardised methods are now needed to quantify the potential effect of the gut microbiome on cancer risk. Although, studying the direct relationship between the gut microbiome and colorectal cancer risk is currently not possible due to the lack of prospective studies with prediagnostic fecal samples, this thesis provided informative insights on the association between the gut microbiome and some parameters of metabolic health that are recognised as colorectal cancer risk factors. Finally, the evaluation of microbiome stability and accuracy in fecal samples collected using different methods employed in ongoing colorectal cancer screening programs indicated that commonly used fecal sample collections such as fecal immunotests and paper-based collection cards are, in general, suitable media for microbiome measurements though storage factors such as ambient temperature can impact on stability for some methods. In addition, the opportunistic collection of fecal samples in fecal immunochemical test tubes after colorectal cancer screening is likely a viable method for establishing cohorts with prediagnostic fecal specimens. In conclusion, this

thesis presents the state-of-the-art on epidemiological evidence for the role of the microbiome in tumorigenesis, provides novel insights on the association of metabolic risk factors for colorectal cancer with the gut microbiome in population-based studies, and finally has generated important methodological data on the impact of fecal sample collection tools on microbial measurements that is needed for future epidemiological research on the microbiome and colorectal cancer, as well as other chronic diseases.

| Embase: | |
| #1 | Neoplasm |
| #2 | Cancer |
| #3 | Microbiome |
| #4 | #1 or #2 and #3 |
| The Cochrane Library search strategy: | |
| #1 | Intestinal bacteria |
| #2 | cancer |
| #3 | intestinal microbiome |
| #4 | #2 and #3 |
| #5 | neoplasm |
| #6 | neoplasia |
| #7 | microbiome |
| #8 | microflora |
| #9 | microbiota |
| #10 | (#2 or #5 or #6) and (#7 or #8 or #9) |

*Search strings containing keywords and database-specific terms (MeSH, Emtree terms and exploded terms) were decided after testing different searches using neoplasms, cancer, microbiome, microflora and several synonyms as main concepts. The Cochrane library was consulted to assure completeness of the literature search.

Supplementary Table S2: Criteria used for the quality assessment - Newcastle Ottawa Scale

| | |
|----------------------|--|
| Selection | Proper selection of study population |
| | 1 Case definition adequate |
| | 2 Representativeness of the cases |
| | 3 Selection of controls |
| | 4 Definition of controls |
| Comparability | Comparability of the study groups |
| | Studies that controlled for age, sex and traditional confounders typical for the |
| | 5 cancer site under study (e.g. smoking for most cancers) |
| | Studies that controlled for other relevant/important confounders (considering |
| | 6 the cancer site; e.g. breast feeding for breast cancer) |
| Exposure | Ascertainment of the exposure or outcome of interest |
| | 7 Ascertainment of exposure |
| | 8 Same method of ascertainment for cases and controls |
| | 9 Non-response rate |

Supplementary Table S3: The design of the studies used in the articles, presenting sample size, age and origin of participants and adjustments available for analyses. The term “case control samples” is used for studies using adjacent normal tissue from the same subject as controls.

| RESEARCH ARTICLE | ANALYSED MICROBIOME | DEFINITION OF THE CASES | SAMPLE SIZE | MEAN AGE OF PARTICIPANTS | ORIGIN OF SUBJECTS | EXCLUSIONS | CONFOUNDERS/ADJUSTMENTS |
|---|---------------------|-------------------------|---|--|--------------------|--|---|
| Liu, 2018 Case control | Airway microbiome | Lung cancer | 24 lung cancer patients with unilateral lobar masses (paired samples from cancerous site and the contralateral noncancerous site) and 18 healthy controls undergoing bronchoscopies | Lung cancer: 60.58 Controls: 56.61 | China | chemotherapy, radiation therapy, undergoing surgery or other treatments for lung cancer before bronchoscopy, antibiotics in the prior 3 months | Gender, Age, BMI, Smoking, Tumor characteristics |
| Tsay, 2018 Case control | Airway microbiome | Lung cancer | 39 subjects with final lung cancer diagnoses and 36 subjects with non-cancer diagnoses, 10 healthy control subjects | 61.2 years | USA | prior history of cancer or recent (1 mo) antibiotic use | age, gender, race, smoking status, pack-years, diagnosis |
| Lee, 2016 Cohort | Lung microbiome | Lung cancer | 28 patients were included in this study; 20 patients were diagnosed with lung cancer, and 8 were diagnosed with a benign mass-like lesion | 64 ± 11 years | South Korea | less than 20 years of age, pregnant, or had undergone any procedure other than bronchoscopy to evaluate the lung mass. | Demographic and clinical data, including age, gender, body mass index (BMI), pulmonary function, smoking status, smoking amount, comorbidities, and final diagnosis |
| Carpagnano, 2014 Case control | Lung microbiome | Lung cancer cases | 43 pat. with non-small cell lung cancer (NSCLC) and 21 healthy controls (H). | (NSCLC) 68.4 years [±SD 9.2], (H) 64.1 years [±SD 13.1]. | Italy | | Adjustments for sex, age, histotype, stage, smoking habit, pack years, time since quitting smoking in subjects with fungal colonization. |
| Hosgood, 2014 Case control | Lung microbiome | Lung cancer cases | 8 never smoking female lung cancer pat. (LC) and 8 never | The age range of (LC) and (H) was 45-72 years. | China | *controls previously diagnosed with lung cancer °smokers | Case-control matching by age and hospital |

| RESEARCH ARTICLE | ANALYSED MICROBIOME | DEFINITION OF THE CASES | SAMPLE SIZE | MEAN AGE OF PARTICIPANTS | ORIGIN OF SUBJECTS | EXCLUSIONS | CONFOUNDERS/ADJUSTMENTS |
|---|--------------------------|--------------------------|---|--|--------------------------------|---------------|--|
| Cameron, 2017 Case control | Sputum microbiome | Lung cancer | 10 patients referred with possible LC, of which four were eventually diagnosed with LC), and six had no LC after one year. smoking female healthy controls (H). | Cases: 58.8 (14.8) Controls: 73.3 (7.2) | UK | Not available | Smoking status, Antibiotic use, CO level (ppm), FEV1% of Predicted |
| Aviles-Jimenez, 2016 Case control | Bile duct microbiome | Cholangiocarcinoma cases | 200 subjects: 100 pat. with extrahepatic cholangiocarcinoma (ECCA) and 100 pat. with benign pathology of the common bile duct (BBP). | (ECCA) 66.2 years [range 50-82 years], (BBP) 53.1 years [range 23-83]. | Mexico | | Case-control matching for sex, age (\pm 5 years) and place of residence + clinical variables incl. the time of evolution of lithiasis, H. bilis/ H. hepaticus infection, sex, age or body mass index. |
| Chng, 2016 Case control | Bile duct microbiome | Cholangiocarcinoma cases | 60 pat. with cholangiocarcinoma (CCA) and adjacent matched normal samples, 5 non-cancer hepatic samples, 2 bile fluid samples and 4 non-cancer gastric mucosa samples (non-CCA). Of the CCA, 28 pat. are Opisthorchis viverriniviverrini associated (OVA), and 32 pat. are not (non-OVa). | (CCA OVA) 57.9 years [range 38-71], (CCA non-OVa) 56.6 years [range 33-69]. For the other samples, mean age is 59.6 years [range 46-82]. | Thailand, Singapore or Romania | | Case-control matching for age, gender and anatomical subtype. |
| Hieken 2016 Case control | Breast tissue microbiome | Breast cancer cases | 28 pat. of whom 13 benign non-atypia breast disease and | Benign patients median [range] age: 49 years | USA | | Adjustments for contamination from the skin, batch effects |

| RESEARCH ARTICLE | ANALYSED MICROBIOME | DEFINITION OF THE CASES | SAMPLE SIZE | MEAN AGE OF PARTICIPANTS | ORIGIN OF SUBJECTS | EXCLUSIONS | CONFOUNDERS/ADJUSTMENTS |
|---|--------------------------|-----------------------------|--|---|--------------------|---|--|
| Urbaniak 2016 Case control | Breast tissue microbiome | Breast cancer cases | 15 invasive breast cancer | [33–70] Breast cancer pat.: 75 years [44–84] Age range [19–90 years] Benign patients median age: 36 years IBC patients median age: 62 years Healthy controls median age: 53 years | Canada | | Adjustments for contamination from the skin, batch effects |
| Audirac-Chalifour, 2016 Case control | Cervical microbiome | Cervical cancer cases | 32 subjects: 8 with cervical cancer and HPV+ (CC), 4 with squamous intraepithelial lesions and HPV+ (SIL) and 20 healthy controls with no cervical lesions (H): 10 HPV- and 10 HPV+. | (CC) 43 years [±SD 11], (SIL) 40 years [±SD 14], (H) 34 years [±SD 8]. | Mexico | <ul style="list-style-type: none"> °insufficient reads °patient's recruitment on the same day of menstrual period ° the non-use of douches and no sexual activity in previous days of the sampling °records of used medication in the last 30 days previous to sampling °molecular HPV+ diagnosis. | Adjustments for age, parity, contraceptive method and HPV-genotype. |
| Oh, 2015 Case control | Cervical microbiome | Cervical cancer cases (CIN) | 120 women: 70 with cervical intraepithelial neoplasia (CIN) 55 CIN1, 15 CIN2 or CIN3, and 50 healthy controls (H). | 42 subjects younger than 39 years, 37 between 40 and 49 years, 30 subjects between 50 and 59 years and 12 subjects 60 years or older. | Korea | <ul style="list-style-type: none"> °history of gynecological cancers, °insufficient data on the questionnaire °inadequate blood for evaluation, chronic disease, drug dependency, °psychological problems. | Adjustments for age, marital status, menopause, smoking status, oral contraceptive use and histological grade but not significant. |
| Seo, 2016 Case control | Cervical microbiome | Cervical cancer cases (CIN) | 137 subjects: 65 pat. with cervical intraepithelial | 43.6 years [±SD 11.2]. | South Korea | <ul style="list-style-type: none"> °histories of gynecologic cancers, chronic diseases, drug | Adjustments for daily intake of nutrients, age, BMI, marital status, menopausal status, |

| RESEARCH ARTICLE | ANALYSED MICROBIOME | DEFINITION OF THE CASES | SAMPLE SIZE | MEAN AGE OF PARTICIPANTS | ORIGIN OF SUBJECTS | EXCLUSIONS | CONFOUNDERS/ADJUSTMENTS |
|---|-----------------------|-------------------------|--|--------------------------|--------------------|---|---|
| Mannell, 1983 Case control | Esophageal microbiome | Esophageal cancer cases | neoplasia (CIN), from who 50 pat. with CIN1 and 15 with CIN2 or CIN3, and 72 healthy controls (H). 101 subjects: 50 pat. with esophagus carcinoma (EC) and 51 healthy controls (H). | Not mentioned. | South Africa | dependencies, or psychological problems *insufficient data on the questionnaire or in specimens. | smoking status, alcohol drinking status, oncogenic HPV infection, monthly family income, parity and oral contraceptive use. |
| Wang, 2016 Case control | Gastric microbiome | Gastric cancer | 315 patients, including 212 patients with chronic gastritis and 103 patients with gastric cancer | 55.8±13.5 years | China | endoscopic findings of peptic ulcer, polyps, or any other local lesions ; Patients who showed histological evidence of atrophy or intestinal metaplasia | Not available |
| Castañero-Rodríguez, 2017 Case control | Gastric microbiome | gastric cancer | gastric cancer (GC, n = 12) and controls (functional dyspepsia (FD), n = 20) | Not available | Singapore/Malaysia | Subjects who had been prescribed antibiotics, non-steroidal anti-inflammatory drugs (NSAIDs) or acid suppressants in the two-month period prior to recruitment as well as subjects known to be infected with the Human Immunodeficiency Virus (HIV) | age, gender or country of origin |
| Li, 2017 Case control | Gastric microbiome | Gastric cancer | 33 individuals including 9 subjects with HP-associated chronic gastritis, 9 gastric intestinal metaplasia, 7 gastric adenocarcinoma | Not available | China | active gastroduodenal ulcers on endoscopy, acid suppressive therapy including PPIs and histamine (H2)-receptor blocker, NSAIDs, anti- | age, gender, HP state, sampling location, and HP-eradication |

| RESEARCH ARTICLE | ANALYSED MICROBIOME | DEFINITION OF THE CASES | SAMPLE SIZE | MEAN AGE OF PARTICIPANTS | ORIGIN OF SUBJECTS | EXCLUSIONS | CONFOUNDERS/ADJUSTMENTS |
|---|---------------------|-------------------------|--|---|--------------------|---|--|
| | | | and 8 HP-negative controls | | | coagulants, anti-platelet medications, antibiotics within recent four weeks, upper gastrointestinal endoscopy, prior gastric surgery or HP eradication treatment | |
| Yu, 2017 Case control | Gastric microbiome | Gastric cancer | 80 paired samples (non-malignant and matched tumor tissues) collected from GC patients | median 62 (58–67) | China | Not available | Alcohol and pickled vegetable consumption, history of cancer, tumor grade and stage, metastasis, survival (days) |
| Yu, 2017 Case control | Gastric microbiome | Gastric cancer | 160 gastric cancer patients with 80 from China and 80 from Mexico | Chinese cases: 60.8 years old Mexican cases: 64.5 years old | China/Mexico | Chinese cases: <18 years old, with cancer other than GC or with previous treatment for GC Mexican cases: <18 years old, with any autoimmune disease, diabetes, or cancer other than GC, and with a previous treatment for GC | Age, gender, tumoral regions of the stomach, country |
| Coker, 2018 Case control | Gastric microbiome | Gastric cancer | 81 cases; validated in 126 additional cases | Not available | China | Not available | age, gender, H. pylori status and tissue positions |
| Hu, 2018 Case control | Gastric microbiome | gastric cancer | 6 patients with GC and 5 patients with SG | superficial gastritis: 60.5 ± 6.5 years gastric adenocarcinoma: 55.2 ± 5.6 years | China | use of antibiotics within 6 months, receiving chemotherapy or radiotherapy prior to the collection of specimens, the use of proton pump inhibitors or other digestive system drugs within 4 weeks. | Gender, Age, Diabetes, BMI |

| RESEARCH ARTICLE | ANALYSED MICROBIOME | DEFINITION OF THE CASES | SAMPLE SIZE | MEAN AGE OF PARTICIPANTS | ORIGIN OF SUBJECTS | EXCLUSIONS | CONFOUNDERS/ADJUSTMENTS |
|--|---------------------|-------------------------|---|---|--------------------|--|--|
| Liu, 2019 Cohort | Gastric microbiome | Gastric cancer | 276 GC patients without preoperative chemotherapy, 230 normal, 247 peritumoral and 229 tumoral tissues | GC: 61.11 ± 11.82 | China | body mass index (BMI) = weight in kilograms divided by the height in meters squared > 30; use of antibiotics, probiotics, prebiotics, or synbiotics in the previous month; preoperative chemotherapy, radiotherapy, or other biological treatment before gastrectomy | age, gender, weight, height, BMI, complications, tumor localization, tumor differentiation, lauren typing, tumor stage, HP infection, antibiotic use, PPI use, Pre-operative chemotherapy, sample collection |
| Aviles-Jimenez, 2014 Case control | Gastric microbiome | Gastric cancer cases | 15 pat.: 5 pat. with non-atrophic gastritis (NAG), 5 pat. with intestinal metaplasia (IM) and 5 pat. with an intestinal-type of gastric cancer (GC). | (NAG) 44 years [range 32-76], (IM) 67 years [range 60-71], (GC) 70.6 years [range 52-81]. | Mexico | *pat. with immunodeficiency *diabetes or other chronic diseases *pat. who received certain medication during the last three months *pat. who previously received therapy for H. pylori eradication. | Adjustments for sex and age. |
| Seo, 2014 Case control | Gastric microbiome | Gastric cancer cases | 16 pat. with gastric cancer from who two samples each were taken: one sample of the gastric cancer (GC), one of the adjacent normal gastric mucosa (H). | 67.18 years [range 37-75] for the 11 pat whose samples were used for statistical analyses. | South Korea | / | |
| Nasrollahzadeh, 2015 Case control | Gastric microbiome | Esophageal cancer cases | 91 subjects: 19 pat. with esophageal squamous cell carcinoma (ESCC), 18 pat with esophageal squamous dysplasia | (ESCC) and (ESD) 64.5 years [±SD 11.8], (DC) 63.6 years [±SD 14.0] and (HC) 62.1 year [±SD 16.3]. | Iran | *samples < 1000 reads. | Case-control matching for age and sex. |

| Cavarretta, 2017 Case control | Prostate microbiome | Prostate cancer | 16 participants: tumor, peri-tumor, and nontumor tissues after radical prostatectomy | Not available | Italy | self-reported lower urinary tract symptoms or a pathologic International Prostate Symptom Score were excluded | diet, lifestyle |
| Salava, 2016 Case control | Skin microbiome | Skin cancer | 15 cutaneous melanomas and 17 benign melanocytic nevi | Melanomas: 69.1 ± 16.9 Melanocytic nevi: 52.9 ± 17.6 | Finland | unsuitable lesion type (dysplastic nevus or other), or insufficient amount of DNA in the samples. | Not available |
| Bučević Popović, 2018 Case control | Urinary microbiome | Bladder cancer | 12 male patients diagnosed with bladder cancer, and from 11 healthy, age-matched individuals | Not available | Croatia | positive history of sexually transmitted or recent urinary infections, diabetes and obesity | Not available |
| Bi, 2019 Case control | Urinary microbiome | Bladder cancer | 29 bladder cancer patients and 26 non-cancer patients | 67.4 years | China | Not available | Not available |

Supplementary Table S4: The results of the articles included in the systematic review, presenting the quality assessment, microbiome measurement and composition and the differences between cases and controls.

| RESEARCH ARTICLE | Abbreviations for cases & controls | ANALYSED SPECIMEN | ANALYSED MICROBIOME | MEASUREMENT OF THE MICROBIOME | MICROBIAL COMPOSITION ALTERATION | OUTCOME | QUALITY OF THE ARTICLE |
|--|--|---|---------------------|---|---|--|--|
| Liu, 2018 Case control | (LC) Lung cancer (H) Healthy controls | Protected bronchial specimen brushing samples | Airway microbiome | 16S rRNA gene sequencing (V3-V4 region) | (LC) ↑ Streptococcus (H) ↑ Staphylococcus | lung cancer-associated microbiota profile is distinct from that found in healthy controls, and the altered cancer-associated microbiota is not restricted to tumor tissue | Selection: **** Comparability: ** Exposure: ** Total NOS score: 8 |
| Tsay, 2018 Case control | (LC) Lung cancer (NLC) Non-cancer diagnoses (H) Healthy controls | Airway brushings | Airway microbiome | 16S rRNA gene sequencing (V4 region) | (LC) ↑ Streptococcus and Veillonella | several transcriptomic signatures previously identified as relevant to lung cancer pathogenesis are associated with enrichment of the lower airway microbiota with oral commensals | Selection: **** Comparability: ** Exposure: ** Total NOS score: 8 |
| Lee, 2016 Cohort | (LC) Lung cancer (BML) Beghin mass-like lesion | Bronchoalveolar fluid | Lung microbiome | 16S rRNA gene sequencing (V1-V3 region) | (LC) ↑ Firmicutes, TM7, Veillonella, Megasphaera | Number of OTUs: higher in LC compared to BML Chao 1 and Shannon: higher in LC compared to BML | Selection: **** Comparability: ** Exposure: ** Total NOS score: 8 |
| Carpagnano, 2014 Case control | (NSCLC) Non-small cell lung cancer, (H) Healthy controls. | Exhaled breath condensate (EBC) and bronchial brushing. | Lung microbiome | Subculturing of the colonies and incubated using 3 different agars. | 12 of the (NSCLC): colonized with fungi. 0 of the (H) colonized. Mostly Aspergillus niger (5), by Aspergillus ochraceus (3) and Penicillium spp. (4). | Fungal colonization by Aspergillus niger, Aspergillus ochraceus and Penicillium spp. in the EBC of (NSCLC) and not of the (H). | Selection: **** Comparability: ** Exposure: ** Total NOS score: 8 |

|---|---|---------------------------|---------------------|--|--|--|--|
| Hosgood, 2014 Case control | (LC) Lung cancer, (H) Healthy controls. | Buccal and sputum samples | Lung microbiome | DNA extraction and 16S rRNA gene analysis of the V1-V2 region. | All buccal samples: mainly Bacteroidetes; Firmicutes, Proteobacteria, Actinobacteria, and Fusobacteria. Sputum of (LC): ↑ Granulicatella, Abiothrophia and Streptococcus. No difference in the lung microbiota between the controls from Laibin and of Reshui, but a difference in the cancer pat. from those two villages. Reshui: ↑ Proteobacteria, ↑ Neisseria, ↓ Bacilli and Streptococcus. | Clear differences between the sputum samples of (LC) and (H). | Selection: **** Comparability: ** Exposure: ** Total NOS score: 8 |
| Cameron, 2017 Case control | (LC) Lung cancer | Sputum samples | sputum microbiome | 16S rRNA gene sequencing | (LC) ↑ Granulicatella adiacens correlated with Enterococcus sp. 130, Streptococcus intermedius, Escherichia coli, S. viridans, Acinetobacterjunii, and Streptococcus sp. 6 | Spontaneous sputum appears to be a viable source of bacterial biomarkers which may have utility as biomarkers for LC status and stage. | Selection: *** Comparability: ** Exposure: ** Total NOS score: 7 |

|--|---|---|--------------------------|---|---|---|--|
| Aviles-Jimenez, 2016 Case control | (ECCA) Extrahepatic cholangiocarcinoma (BBP) benign pathology of the common bile duct | Epithelial cells of the bile duct | Bile duct microbiome | DNA extraction and 16S rRNA gene analysis of the V4 region + PCR. | All groups: mainly Proteobacteria. (ECCA) ↑ Fusobacteria, Acidobacteria and Planctomycetes, ↑ Methylophilaceae, Fusobacterium, Prevotella, Helicobacter and Campylobacter, ↓ Neisterenkonnia, Rothia and Mesorhizobium. | Significant separation between (ECCA) and (BBP) was observed. | Selection: **** Comparability: ** Exposure: ** Total NOS score: 8 |
| Chng, 2016 Case control | (CCA) Cholangiocarcinoma (Ova) Opisthorchis viverrini associated | Tissue samples of the liver, of the bile duct, bile fluid samples and gastric mucosa samples. | Bile duct microbiome | DNA extraction and 16S rRNA gene analysis of the V3-V6 region. | (CCA) dominated by Dietziaceae, Pseudomonadaceae, Oxalobacteraceae. (CCA) normal tissue ↑ Enterobacteriaceae, Lachnospiraceae, Sphingomonadaceae and Bifidobacteriaceae. (CCA) cancer tissue ↑ Stenothrophomonas. | Gastric tissue microbiome was clearly distinguishable from the bile duct. (CCA) tumor tissue ~ adjacent normal tissue. Significant differences with the controls. | Selection: **** Comparability: ** Exposure: ** Total NOS score: 8 |
| Hieken 2016 Case control | (BBD-non-atypia) Benign breast disease without atypia, (IBC) Invasive breast cancer | Breast tissue | Breast tissue microbiome | DNA extraction and 16S rRNA gene analysis of the V3-V5 region. | (IBC) ↑ Fusobacterium, Atopobium, Hydrogenophaga, Gluonacetobacter and Lactobacillus | Significant differences in microbial composition of breast tissue in benign vs. malignant disease. | Selection: **** Comparability: ** Exposure: ** Total NOS score: 8 |

| RESEARCH ARTICLE | Abbreviations for cases & controls | ANALYSED SPECIMEN | ANALYSED MICROBIOME | MEASUREMENT OF THE MICROBIOME | MICROBAL COMPOSITION ALTERATION | OUTCOME | QUALITY OF THE ARTICLE |
|---|---|--|--------------------------|--|--|--|--|
| Urbaniak 2016 Case control | (BBC) Benign breast cancer (IBC) Invasive breast cancer (H) Healthy controls | Breast tissue | Breast tissue microbiome | DNA extraction and 16S rRNA gene analysis of the V6 region. | (IBC) ↑ Enterobacteriaceae, Bacillus and Staphylococcus | Significant differences in microbial composition of breast tissue in healthy controls vs. malignant disease. | Selection: **** Comparability: ** Exposure: ** Total NOS score: 8 |
| Audirac-Chalifour, 2016 Case control | (CC) Cervical cancer, (SIL) Squamous intraepithelial lesions (H) Healthy controls with no cervical lesions | Cervical scraping swabs and fresh cell biopsies. | Cervical microbiome | DNA extraction and 16S rRNA gene analysis of the V3-V4 region. | (CC) characterised by presence of Sneathia spp. and Fusobacterium spp. and absence of organisms from the Bifidobacteriaceae family. (CC) ↓ Lactobacillus crispatus, Lactobacillus iners and Gardnerella vaginalis, ↑ Fusobacterium necrophorum. (SIL) dominated by Fusobacterium spp, Sneathia spp., Shuttleworthia satelles and Megasphaera spp. | Higher alpha diversity in the (SIL) group and (CC) group than in the (H) + notably different beta diversity in every stage of cervical cancer. | Selection: **** Comparability: ** Exposure: * Total NOS score: 7 |
| Oh, 2015 Case control | (CIN) Cervical intraepithelial neoplasia (H) Healthy controls. | Cervical swab | Cervical microbiome | DNA extraction and 16S rRNA gene analysis of the V1-V3 region. | All groups: dominated by Firmicutes, Actinobacteria, Bacteroidetes, Proteobacteria, Tenericutes, Fusobacteria, and candidate division TM7. Predominance of A. vaginalis, L. iners and G. vaginalis and paucity of L. crispatus = risky microbial pattern. Synergistic effect of risky microbial pattern with high risk HPV infection on CIN risk. Different A. vaginalis | (CIN): higher numbers of OTU. | Selection: **** Comparability: ** Exposure: ** Total NOS score: 8 |

|---|---|----------------------|-----------------------|---|---|---|--|
| | | | | | and <i>L. crispatus</i> ratio between (H) and (CIN). | | |
| Seo, 2016 Case control | (CIN) Cervical intraepithelial neoplasia | Cervical swab | Cervical microbiome | DNA extraction and 16S rRNA gene analysis of the V1-V3 region. | Lactobacillus iners-dominant microbial type B + A, vaginae-dominant microbial type C: ↑ risk of CIN. Synergistic effect between semi-Western diet and microbial type C. No synergistic effect between semi-Western diet and microbial type B. | Semi-Western diet: ↑ risk of CIN + synergistically ↑ risk with the dominance of A. vaginae. | Selection: **** Comparability: ** Exposure: ** Total NOS score: 8 |
| Mannell, 1983 Case control | (EC) Esophagus carcinoma (H) Healthy controls. | Esophageal aspirates | Esophageal microbiome | Incubated and then aerobic and anaerobic subculturing onto selective agar media. Identified by their morphology and biochemical reactivity. | (H) and (EC): mainly Streptococcus viridans, Haemophilus influenza and Neisseria catarrhalis, Klebsiella pneumoniae and Streptococcus group B. | No significant difference in the number and type of bacterial species between (H) and (EC). | Selection: *** Comparability: Exposure: * Total NOS score: 4 |

| RESEARCH ARTICLE | Abbreviations for cases & controls | ANALYSED SPECIMEN | ANALYSED MICROBIOME | MEASUREMENT OF THE MICROBIOME | MICROBAL COMPOSITION ALTERATION | OUTCOME | QUALITY OF THE ARTICLE |
|--|------------------------------------|--|---------------------|---|---|--|--|
| Wang, 2016 Case control | (GC) Gastric cancer | gastric mucosa | Gastric microbiome | 16S rRNA gene sequencing (V1-V3 region) | (GC) ↑ Lactobacillus, Escherichia–Shigella, Nitrospirae, Burkholderia fungorum, and Lachnospiraceae | Markedly increased bacterial load in GC; | Selection: *** Comparability: * Exposure: ** Total NOS score: 6 |
| Castañero-Rodríguez, 2017 Case control | (GC) Gastric cancer | Antral gastric biopsies | gastric microbiome | 16S rRNA gene sequencing | (GC) ↑ Lactococcus, Veillonella, and Fusobacteriaceae | enrichment of pro-inflammatory oral bacterial species, increased abundance of lactic acid producing bacteria, and enrichment of short chain fatty acid production pathways in GC | Selection: **** Comparability: * Exposure: ** Total NOS score: 7 |
| Li, 2017 Case control | (GC) Gastric cancer | Endoscopic gastric biopsies | Gastric microbiome | 16S rRNA gene sequencing (V3-V4 region) | (GC) ↑ Flavobacterium, Klebsiella, Serratia marcescens, Stenotrophomonas, Achromobacter and Pseudomonas | GC samples tended to have lower bacterial diversity compared with other samples with similar H. pylori levels. H. pylori colonization results in alterations of gastric microbiota and reduction in bacterial diversity. | Selection: **** Comparability: ** Exposure: ** Total NOS score: 8 |
| Yu, 2017 Case control | (GC) Gastric cancer | gastric tissue | Gastric microbiome | 16S rRNA gene sequencing | (High tumor grade vs. Low tumor grade) ↑ Helicobacter pylori ↓ Bacteroidetes & Lactobacillales | gastric non-malignant tissue microbiota features were associated with a known gastric cancer risk factor (family history of UGI cancer) and clinical features (tumor grade and metastasis) | Selection: *** Comparability: ** Exposure: ** Total NOS score: 7 |
| Yu, 2017 Case control | (GC) Gastric cancer | Paired non-malignant and tumor tissues | Gastric microbiome | 16S rRNA gene sequencing (V3-V4 region) | (GC) ↑ Bacteroidetes, Firmicutes, Fusobacteria, and Spirochaetes ↓ Proteobacteria | Comparison with other body sites suggested that stomach microbiota resembled oral microbiota in phylum-level taxonomical profiles, but not in functional profiles. | Selection: **** Comparability: * Exposure: ** Total NOS score: 7 |

|--|---|----------------------|---------------------|--|--|---|--|
| Coker, 2018 Case control | (SG) Superficial gastritis (AG) atrophic gastritis (IM) intestinal metaplasia (GC) Gastric cancer | gastric mucosa | Gastric microbiome | 16S rRNA gene sequencing (V4 region) | (GC) ↑ 21 bacterial taxa, including Peptostreptococcus stomatis, Streptococcus anginosus, Parvimonas micra, Slackia exigua and Dialister pneumosintes ↓ 10 bacterial taxa compared to SG | members of oral pathogenic taxa were over-represented and formed strong co-occurrence network in GC compared with other precancerous stages | Selection: *** Comparability: ** Exposure: ** Total NOS score: 7 |
| Hu, 2018 Case control | (SG) Superficial gastritis (GC) Gastric adenocarcinoma | gastric wash samples | Gastric microbiome | Shotgun Metagenomic sequencing | (GC) ↑ Neisseria, Alloprevotella, and Aggregatibacter ↓ Sphingobium yanoikuyae | GC patients was characterized by reduced species richness, enrichment of 13 bacterial taxa and depletion of 31 taxa | Selection: **** Comparability: ** Exposure: ** Total NOS score: 8 |
| Liu, 2019 Cohort | (GC) Gastric cancer | Gastric tissues | Gastric microbiome | 16S rRNA gene sequencing (V3-V4 region) | (GC) ↑ Prevotella melanigenica, Streptococcus anginosus and Propionibacterium acnes ↓ Helicobacter pylori, Prevotella copri and Bacteroides uniformis | the stomach microhabitats determined the overall structure and composition of the gastric microbiota, regardless of different GC stage and type. | Selection: **** Comparability: ** Exposure: ** Total NOS score: 8 |
| Aviles-Jimenez, 2014 Case control | (NAG) Non-atrophic gastritis, (IM) Intestinal metaplasia (GC) Intestinal-type of gastric cancer. | Gastric samples | Gastric microbiome | DNA extraction and 16S rRNA gene analysis (no region mentioned). | Gastric tissue of all groups: mainly Proteobacteria and Firmicutes. (GC) ↑ Lactobacillus coleohominis and Lachnospiraceae, ↓ 2 TM7, 2 Porphyromonas and Neisseria. | Differences between (GC) and (NAG), but not between (IM) and (GC) or (IM) and (NAG). From (NAG) to (IM) to (GC), the microbiota diversity showed a trend to diminish. | Selection: **** Comparability: * Exposure: * Total NOS score: 6 |

| Feng, 2019 Case control | (TC) thyroid carcinoma (H) healthy controls | Stool | Gut microbiome | 16S rRNA gene sequencing (V3-V4 region) | (BC) ↑ 19 genera ↓ 8 genera | Eight metabolites combined with 5 genera were more effective in distinguishing TC patients from H | Selection: **** Comparability: ** Exposure: ** Total NOS score: 8 |
| Gong, 2013 Case control | (LSCC) Laryngeal squamous cell carcinoma, (H) Controls with vocal cord polyps. | Tissue samples of the larynx | Laryngeal microbiome | DNA extraction and 16S rRNA gene analysis of the V1-V3 region. | All samples: mainly Firmicutes, Fusobacteria, Bacteroidetes, Proteobacteria, and Actinobacteria (in that order of frequency) and at genera level Streptococcus, Fusobacterium, Prevotella, Neisseria and Gemella. (LSCC) ↑ Fusobacterium, Prevotella and Gemella ↓ Streptococcus and Rothia. Prevotella and Solobacterium were significantly more prevalent in T3-T4 tumors than T1-T2. | Significantly different microbiomes between (LSCC) and controls. Total NOS score: 5 | Selection: **** Comparability: * Exposure: * Total NOS score: 5 |
| Shin, 2017 Case control | (HNSCC) Head and neck squamous cell carcinoma | Tissues from the oral cavity, larynx-pharynx, and lymph nodes | Oral microbiome | 16S rRNA gene sequencing (V4 region) | (HNSCC) ↑ Fusobacteria and Proteobacteria ↓ Firmicutes, Actinobacteria and Streptococcus | Alpha and beta diversity analyses revealed that normal tissues had the greatest richness in community diversity, while the metastatic populations were most closely related to one another. | Selection: **** Comparability: * Exposure: ** Total NOS score: 7 |
| Wang, 2017 Case control | (HNSCC) Head and neck squamous cell carcinoma | Tumor resection specimens | Oral microbiome | 16S rRNA gene sequencing (V1-V4 region) | (HNSCC) ↑ Parvimonas ↓ Actinomycetes | Shannon, phylogenetic diversity: no significant difference Weighted, unweighted Unifrac: lower in tumor | Selection: **** Comparability: ** Exposure: ** Total NOS score: 8 |

| RESEARCH ARTICLE | Abbreviations for cases & controls | ANALYSED SPECIMEN | ANALYSED MICROBIOME | MEASUREMENT OF THE MICROBIOME | MICROBAL COMPOSITION ALTERATION | OUTCOME | QUALITY OF THE ARTICLE |
|------------------------------------|---|--|---------------------|---|---|--|---|
| Hayes, 2018 Nested case-control | (HNSCC) Head and neck squamous cell carcinoma | mouthwash samples | Oral microbiome | 16S rRNA gene sequencing (V3-V4 region) | (HNSCC) ↓ Corynebacterium, Kingella | oral microbiome may be associated with subsequent risk of HNSCC, with the strongest links for larynx cancer and those with a history of tobacco use | Selection: *** Comparability: ** Exposure: ** Total NOS score: 7 |
| Hu, 2016 Case control | (OSCC) oral squamous cell carcinoma (OLK) oral leukoplakia (H) healthy controls | Nonstimulated saliva | Oral microbiome | 16S rRNA gene sequencing | (OSCC) ↑ Bacillus (OLK) ↑ Bacteroidetes, TM7, Haemophilus ↓ Firmicutes (H) ↑ Streptococcus and Abiotrophia | Chao index: higher richness in OLK compared to HC Shannon and Simpson: higher diversity in OSCC compared to HC | Selection: * Comparability: Exposure: ** Total NOS score: 3 |
| Banerjee, 2017 Case control | (OCSCC/OPSCC) oropharyngeal squamous cell carcinomas | Carcinomas taken from tongue, base of tongue, tonsil, floor of mouth, cheek and predominantly oropharynx | Oral microbiome | Pan-pathogen array technology (PathoChip) coupled with next-generation sequencing | (OCSCC) ↑ Proteobacterias Eshcherichia, Brevundimonas, Comamonas, Alcaligenes, Caulobacter, Cardiobacterium, Plesiomonas, Serratia, Edwardsiella, Haemophilus, Frateuria along with Actinobacteria Rothia and Bacteroidetes Peptoniphilus | The screening of OCSCC samples as well as matched and non-matched controls have identified distinct viral and other microbial signature patterns associated with OCSCC | Selection: **** Comparability: Exposure: ** Total NOS score: 6 |

| RESEARCH ARTICLE | Abbreviations for cases & controls | ANALYSED SPECIMEN | ANALYSED MICROBIOME | MEASUREMENT OF THE MICROBIOME | MICROBAL COMPOSITION ALTERATION | OUTCOME | QUALITY OF THE ARTICLE |
|---|--|--|---------------------|---|---|---|--|
| Lee, 2017 Case control | (OC) oral cancer | saliva samples | Oral microbiome | 16S rRNA gene sequencing (V4 region) | (OC) ↑ <i>Bacillus</i> , <i>Enterococcus</i> , <i>Parvimonas</i> , <i>Peptostreptococcus</i> , and <i>Slackia</i> | the oral microbiome compositions revealed significant differences between epithelial precursor lesion and cancer patients | Selection: *** Comparability: ** Exposure: ** Total NOS score: 7 |
| Mok, 2017 Case control | (C) Cancer (OPMD) Potentially malignant disorders (H) Normal | Swab samples | Oral microbiome | 16S rRNA gene sequencing (V6-V9 region) | (C/OPMD) ↑ <i>Neisseria</i> , <i>Gemella</i> and <i>Granulicatella</i> (H) ↑ <i>Streptococcus</i> and <i>Veillonella</i> | significant difference between the normal and the cancer associated oral microbiota but not between the OPMD and the other two groups | Selection: **** Comparability: Exposure: ** Total NOS score: 6 |
| Wolf, 2017 Case control | (OSCC) Oral squamous cell carcinomas (H) Healthy | saliva samples | Oral microbiome | 16S rRNA gene sequencing | (H) ↑ <i>Bacteroidetes</i> (<i>Prevotella</i>), <i>Proteobacteria</i> (e.g. <i>Haemophilus</i> and <i>Neisseria</i>) and <i>Firmicutes</i> (e.g. <i>Streptococcus</i> and <i>Veillonella</i>) (OSCC) ↑ <i>Actinomyces</i> (<i>Actinobacteria</i>), <i>Schwartzia</i> (<i>Firmicutes</i>), <i>Treponema</i> (<i>Spirochaetes</i>) and <i>Selenomonas</i> (<i>Firmicutes</i>) | differences in microbial abundance and diversity might inform disease status in OSCC patients | Selection: *** Comparability: ** Exposure: ** Total NOS score: 7 |
| Zhao, 2017 Case control | (OSCC) Oral squamous cell carcinomas | Lesion samples and anatomically matched normal samples | Oral microbiome | 16S rRNA gene sequencing (V4-V5 region) | (OSCC) ↑ <i>Fusobacterium</i> , <i>Dialister</i> , <i>Peptostreptococcus</i> , <i>Filifactor</i> , <i>Peptococcus</i> , <i>Catonella</i> and <i>Parvimonas</i> | Significantly greater bacterial diversity was observed in the cancer samples than in the normal samples | Selection: **** Comparability: Exposure: ** Total NOS score: 6 |
| Hsiao, 2018 Case control | (OSCC) Oral squamous cell carcinomas (H) Healthy | saliva samples | Oral microbiome | 16S rRNA gene sequencing (V3-V5 region) | (OSCC) ↑ <i>Prevotella</i> <i>tanneriae</i> , <i>Fusobacterium</i> <i>nucleatum</i> , and <i>Prevotella</i> <i>intermedia</i> | positive association between periodontopathogenic bacteria and OSCC risk and this relationship may be influenced by lifestyle and genetic factors | Selection: **** Comparability: ** Exposure: ** Total NOS score: 8 |

| RESEARCH ARTICLE | Abbreviations for cases & controls | ANALYSED SPECIMEN | ANALYSED MICROBIOME | MEASUREMENT OF THE MICROBIOME | MICROBAL COMPOSITION ALTERATION | OUTCOME | QUALITY OF THE ARTICLE |
|--|---|--|---------------------|---|--|--|--|
| Lim, 2018 Case control | (OCC) Oral cavity cancer and (OPC) oropharyngeal cancers | Oral rinse samples | Oral microbiome | 16S rRNA gene sequencing (V6-V8 region) | (OCC/OPC) ↑ Actinobacillus, Actinomyces, Aggregatibacter, Capnocytophaga, Fusobacterium, Oribacterium, Rothia, Haemophilus, Leptotrichia, Neisseria, Porphyromonas and Veillonella ↓ Paludibacter, Corynebacterium | the oral microbiome is able to predict the presence of OCC and OPC with sensitivity and specificity of 100 and 90% | Selection: **** Comparability: ** Exposure: ** Total NOS score: 8 |
| Perera, 2018 Case control | (OSCC) oral squamous cell carcinoma (FEP) fibroepithelial polyp | fresh biopsies | Oral microbiome | 16S rRNA gene sequencing (V1-V3 region) | (OSCC) ↑ Capnocytophaga, Pseudomonas, and Atopobium, Campylobacter concisus, Prevotella salivae, Prevotella loeschii, and Fusobacterium oral taxon 204 (FEP) ↑ Lautropia, Staphylococcus, and Propionibacterium, Streptococcus mitis, Streptococcus oral taxon 070, Lautropia mirabilis, and Rothia dentocariosa | OSCC tissues tended to have lower species richness and diversity | Selection: **** Comparability: * Exposure: ** Total NOS score: 7 |
| Yost, 2018 Case control | (OSCC) Oral squamous cell carcinoma | tumor biopsy and tumor-adjacent biopsy | Oral microbiome | Metatranscriptomic analysis | (OSCC) ↑ Fusobacteria | Fusobacteria may be the leading phylogenetic group responsible for the increase in expression of virulence factors in the oral microbiome of OSCC patients | Selection: **** Comparability: ** Exposure: ** Total NOS score: 8 |

| RESEARCH ARTICLE | Abbreviations for cases & controls | ANALYSED SPECIMEN | ANALYSED MICROBIOME | MEASUREMENT OF THE MICROBIOME | MICROBAL COMPOSITION ALTERATION | OUTCOME | QUALITY OF THE ARTICLE |
|---|---|--------------------|---------------------|--|---|--|--|
| Börnigen, 2017 Case control | (OSCC) Oral squamous cell carcinomas | Oral rinse samples | oral microbiome | 16S rRNA gene sequencing (V4 region) | (OSCC) ↑ Dialister ↓ Scardovia | Alterations following tooth loss, itself a major risk factor for oral cancer, are likely a result of severe ecological disruption due to habitat loss but may also contribute to the development of the disease. | Selection: **** Comparability: ** Exposure: ** Total NOS score: 8 |
| Schmidt, 2014 Case control | (OC) Oral cancer, (HC) Healthy controls. (CIS) Carcinoma in situ, (PRE) Pre-cancer stages | Oral swab | Oral microbiome | DNA extraction and 16S rRNA gene analysis of the V4 region. | All samples: mainly Firmicutes, Bacteroidetes, Proteobacteria, Fusobacteria and Actinobacteria. (OC2) ↑ Fusobacteria and Bacteroidetes, ↓ Firmicutes and Actinobacteria, ↓ Streptococcus and Rothia, ↑ Fusobacterium and Prevotella. (PRE) ↑ Bacteroidetes and ↓ Streptococcus. | Significant differences between the groups and within the same patient (oral lesions vs. anatomically matched samples). | Selection: *** Comparability: ** Exposure: ** Total NOS score: 7 |
| Berkovitz, 2016 Case control | (OSCC) Oral squamous cell carcinoma. (H) Healthy controls | Oral swab | Oral microbiome | Yeast colonization first by agar plates and incubation, then by macro- and microscopic morphology, catalase test and CHROMagar Candida plates, and finally MALDI-TOF analysis. | All samples: predominant fungal genus was Candida. (OSCC) ↑ frequency of oral yeast colonization, more yeast cells and ↑ fungal burden. | (OSCC): ↑ diversity of fungi. No significant differences in lipase and protease activity. | Selection: **** Comparability: ** Exposure: ** Total NOS score: 6 |

| RESEARCH ARTICLE | Abbreviations for cases & controls | ANALYSED SPECIMEN | ANALYSED MICROBIOME | MEASUREMENT OF THE MICROBIOME | MICROBAL COMPOSITION ALTERATION | OUTCOME | QUALITY OF THE ARTICLE |
|---|---|-------------------|---------------------|--|--|--|---|
| Henrich, 2014 Case control | (FAC) Fanconi Anaemia and oral squamous cell cancer. (FAB) Fanconi Anaemia and benign oral lesion (H) Healthy controls. | Oral swab | Oral microbiome | DNA extraction and 16S rRNA gene analysis of the V1-V2 region, as well as a Candida-specific qPCR. | All (FAC) samples: mainly Bacteroidetes, Firmicutes, Proteobacteria and Tenericutes. All (FAB) and (H): mainly Actinobacteria, Bacterioidetes, Firmicutes and Proteobacteria. (FAC) ↑ Mycoplasmataceae (M. salivarium), Pseudomonadaceae, P. salivae and Prevotella spp., ↓ Streptococcus, Rothia mucilaginosa. All (FAC): Candida positive, all other samples Candida negative. | (FAC) ↓ diversity, microbiota was getting less diverse the more the samples are moving into a tumourous state. | Selection: * Comparability: ** Exposure: ** Total NOS score: 3 |
| Homann, 2000 Case control | (T) Malignant tumor of the oral cavity. (A) Alcoholics. (DE) Dental examination or treatment. (UN) Unemployed volunteers. (H) Healthy volunteers. | Saliva | Oral microbiome | Head space gas chromatography (GC) + several specific and non-specific agar media. | High acetaldehyde producers (especially smokers and heavy drinkers): ↑ count of aerobes like Streptococcus salivarius, Streptococcus viridans, Corynebacterium sp., Stomatococcus sp., and yeasts (higher concentration + more frequently), also ↑ count of anaerobes. No bacterial species was significantly more frequent among the low producers. | Significant differences between high and low producers. Smoking and heavy alcohol intake are strong predictors of microbial acetaldehyde production. | Selection: *** Comparability: ** Exposure: ** Total NOS score: 7 |

| Chen, 2015 Case control | (ESCC) Esophageal squamous cell carcinoma. (DYS) Dysplasia. (H) Healthy controls. | Saliva | Oral microbiome | DNA extraction and 16S rRNA gene analysis of the V3-V4 region. | All samples: mainly Bacteroidetes, Firmicutes, Proteobacteria, Fusobacteria, and Actinobacteria (in order of frequency). (ESCC): ↑ Prevotella, Streptococcus and Porphyromonas, ↓ Megaspheera, Aggregatibacter, Atopobium, Lautropia, Actinobacillus, Bulleidia, Catonella, Filifactor, Corynebacterium, TG5, Acholeplasma, Moryella, Butyrivibrio, Dialister, Peptococcus, and Cardiobacterium. (ESCC) compared to (DYS) ↓Lautropia, Bulleidia, Catonella, Corynebacterium, Moryella, Peptococcus and Cardiobacterium. | Significant difference in OTU diversity and richness. (ESCC): ↓ microbial diversity. ↓ Streptococcus ~ ↑ TNM stage, ↑ Lactobacillus ~ ↑ TNM stages. | Selection: **** Comparability: ** Exposure: ** Total NOS score: 8 |
| Olson, 2017 | (PDAC) pancreatic ductal adenocarcinoma (IPMN) intraductal papillary mucinous neoplasms (H) healthy controls | Saliva samples | Oral microbiome | 16S rRNA gene sequencing (V4-V5 region) | (PDAC) ↑ Firmicutes (H) ↑ Proteobacteria | no differences in diversity of the oral microbiota among these groups, there were differences in the mean relative proportions of some taxa | Selection: **** Comparability: ** Exposure: ** Total NOS score: 8 |

| RESEARCH ARTICLE | Abbreviations for cases & controls | ANALYSED SPECIMEN | ANALYSED MICROBIOME | MEASUREMENT OF THE MICROBIOME | MICROBAL COMPOSITION ALTERATION | OUTCOME | QUALITY OF THE ARTICLE |
|---|--|-------------------|---------------------|--|--|--|--|
| Fan, 2018 Case control | (PC) pancreatic cancer | oral wash samples | Oral microbiome | 16S rRNA gene sequencing (V3-V4 region) | (PC) ↑ Porphyromonas gingivalis and Aggregatibacter actinomycetemcomitans ↓ Fusobacteria, Leptotrichia | The oral microbiota may play a role in the aetiology of pancreatic cancer. | Selection: *** Comparability: ** Exposure: ** Total NOS score: 7 |
| Fan, 2016 Prospective nested case control | (PAD) Primary pancreatic adenocarcinoma. (H) Matched controls. | Oral mouthwash | Oral microbiome | DNA extraction and 16S rRNA gene analysis of the V3-V4 region. | P.gingivalis: associated with ↑ risk of pancreatic cancer (OR 1.6) for low relative abundance and high relative abundance, thus showing a dose-response relationship. A. actinomycetemcomitans: associated with ↑ risk of pancreatic cancer (OR 2.20), more in ever-drinkers (OR 3.03) than in never-drinkers (OR 0.47). Fusobacteria and its genus Leptotrichia: associated with ↓ pancreatic cancer risk (OR 0.94). | Carriage of the periodontal pathogens P. gingivalis and A. actinomycetemcomitans and ↓ relative abundance of Fusobacteria and its genus Leptotrichia, were associated with subsequent risk of pancreatic cancer, unlikely due to smoking or other confounders. | Selection: **** Comparability: ** Exposure: ** Total NOS score: 8 |

| RESEARCH ARTICLE | Abbreviations for cases & controls | ANALYSED SPECIMEN | ANALYSED MICROBIOME | MEASUREMENT OF THE MICROBIOME | MICROBAL COMPOSITION ALTERATION | OUTCOME | QUALITY OF THE ARTICLE |
|---|---|-------------------|---------------------|---|--|--|---|
| Farrell, 2012 Case control | (PC) Pancreatic cancer. (H) Matched controls. (CP) Chronic pancreatitis | Saliva | Oral microbiome | DNA extraction and 16S rRNA gene analysis using universal primers + HOMIM array was used for profiling. | All samples: mainly Firmicutes, Proteobacteria, Bacteroidetes and Actinobacteria. (PC1): ↑ 31 species/clusters and ↓ 25. Potential biomarker candidates: Streptococcus, Prevotella, Campylobacter, Granulicatella, Atopobium and Neisseria. (PC2): ↓ Streptococcus and Neisseria, ↑ Granulicatella. (CP): ↓ Streptococcus and ↑ Granulicatella, compared to (PC2). | Significant differences between (PC) and (H). Using Streptococcus and Neisseria as biomarker: 96.4% sensitivity and 82.1% specificity for distinguishing patients with pancreatic cancer from healthy subjects. Using Streptococcus and Granulicatella: 85.7% sensitivity and 55.6% specificity. | Selection: *** Comparability: ** Exposure: ** Total NOS score: 7 |
| Torres, 2015 Case control | (PC) Pancreatic cancer. (OD) Other diseases. (H) Healthy controls | Saliva | Oral microbiome | DNA extraction and 16S rRNA gene analysis using a 'universal' bacterial primer 515F + qPCR. | All samples: mainly Proteobacteria, Actinobacteria, Bacteroidetes, Firmicutes, and Fusobacteria. (PC): ↑ Leptotrichia, ↓ Porphyromonas and Neisseria. No difference in Streptococcus or Granulicatella between (PC) and (H). (PC): ↑ abundance ratio of Neisseria to Porphyromonas. | Significant differences in microbiome between (PC) and (H). No differences among the 3 main groups in beta diversity or alpha diversity. The Leptotrichia to Porphyromonas ratio as a potential diagnostic biomarker for pancreas cancer. | Selection: *** Comparability: ** Exposure: ** Total NOS score: 5 |

| Hu, 2015 Case control | (GC) Gastric cancer, (H) Healthy controls, (GCtn) Gastric cancer, thin coatings, (GCtk) Gastric cancer, thick tongue coatings | Tongue coating samples and images | Oral microbiome | DNA extraction and 16S rRNA gene analysis of the V2-V4 region. | All samples: mainly Firmicutes; Proteobacteria, Bacteroidetes, Actinobacteria, Fusobacteria, and TM7. (GC): ↑ Actinobacteria and ↓ Proteobacteria, ↓ Fusobacterium, Neisseria, Haemophilus and Porphyromonas. (GCtn): mainly Prevotella, Veillonella, Leptotrichia, Lactococcus, and Streptococcus. (GCtk): mainly Prevotella, Streptococcus, Actinomyces, Veillonella, and Leptotrichia, ↑ Actinomyces and Streptococcus compared to the others. | Significant difference in the thickness of tongue coating. (GCtk) significantly ↓ microbial community diversity. | Selection: **** Comparability: ** Exposure: ** Total NOS score: 8 |
| Banerjee, 2017 Case control | (OC) Ovarian cancer | Ovarian cancer samples | Ovarian microbiome | Pan-pathogen array technology (PathoChip) coupled with next-generation sequencing | (OC) ↑ Streptococcus, Staphylococcus, Bacillus, Mycoplasma, Chlamydia, Pedicoccus, Chyseeobacterium, Fusobacterium, Prevotella, Escherichia, Treponema | A distinct group of viral, bacterial, fungal and parasitic signatures of high significance in ovarian cases | Selection: **** Comparability: Exposure: ** Total NOS score: 6 |
| Gong, 2017 Case control | (LC) laryngeal carcinoma (VCP) vocal cord polyps | swab samples | Pharyngeal microbiome | 16S rRNA gene sequencing (V1-V2 and incomplete V3 region) | no difference in bacterial communities in the pharynx from patients with LC and VCP | Inverse correlations were found between Streptococcus and other bacterial communities, suggesting that potential antagonism may exist among pharyngeal microbiota | Selection: ** Comparability: * Exposure: ** Total NOS score: 5 |
