cancer épithélial de l'ovaire**

Thèse présentée et soutenue à Besançon, le Mardi 28 Novembre 2023

**Composition du Jury :**

M. ADOTEVI Olivier	Professeur, Université de Bourgogne-Franche-Comté	Président
Mme. VAN LINT Carine	Professeure, Université Libre de Bruxelles	Rapporteuse
M. SCHWARTZ Christian	Professeur, Université de Strasbourg	Rapporteur
M. HERBEIN Georges	Professeur, Université de Bourgogne-Franche-Comté	Directeur de thèse

**Invités**

Mme. DIAB-ASSAF Mona Professeure, Université Libanaise

## Acknowledgement

*As I reach the culmination of my academic journey with this thesis, I would like to express my profound gratitude to the following individuals and entities who have played a pivotal role in my PhD journey.*

*First and foremost, I would like to praise and thank GOD, the almighty, who has granted me countless blessings, strength, perseverance, knowledge, and opportunities so that I have been finally able to accomplish my thesis.*

*I sincerely thank Pr. Georges Herbein, my supervisor, for providing me with the opportunity to pursue the PhD under his supervision. I'm beyond grateful for the exceptional support, guidance, presence, and knowledge you've shared with me during my thesis research. Your mentorship has been an invaluable and transformative part of my academic experience. Your supportive input and constructive feedbacks propelled me forward, broaden my knowledge, and challenged me to strive highest standards. Not to forget your presence, both in terms of physical presence during meetings and your willingness to be available when needed, has made a world of difference.*

*My gratitude knows no bounds for Pr. Mona Diab-Assaf. I appreciate her recommendation to Pr. Georges Herbein, which led to my acceptance as a PhD candidate in his laboratory. Throughout this journey, she offered continuous positive reinforcement and support.*

*I am extremely thankful to the members of my PhD jury including Pr. Olivier Adotevi, Pr. Carine Van Lint, and Pr. Christian Schwartz. I am well aware of the time you invested in reading my manuscript, providing feedback, and offering your expertise which significantly enhanced the quality of this research.*

*I am indebted to Apex Biosolutions company and the Hariri Foundation for Sustainable Human Development for their financial assistance that contributed to the successful completion of my PhD.*

*I extend my heartfelt thanks to my lab colleagues (Sébastien, Zeina, Sandy, Jihan, and Fidaa) for being an essential part of my academic journey. A special thanks to Sébastien who facilitated my integration into the lab environment and acquainted me with various laboratory methods. Thank you for your willingness to share your scientific knowledge and experience with me. I also deeply acknowledge the support of Jihan and Fidaa. I'm thankful for their friendship and encouragement. To all my lab colleagues, may your paths ahead be filled with success, growth, and endless opportunities. Here's to each of you and the bright futures you're destined to create. Here's to your ambitions!*

*To my guardians, “Baba Yehya” and “Mama Ghada”, thank you for being the pillar of my PhD journey. You have provided me with strength during life’s triumphs and tribulations; you amplified the joy during my successes. Knowing that I can count on you, no matter what, has been a priceless gift. I am forever grateful for your irreplaceable presence in my life. To my gems, my brother “Zakaria” and my sister ”Wafaa”, your love, support, empathy, listening ear, and words of encouragement have been a source of solace and strength. My love for all of you goes beyond what words can convey. I truly cherish our bond and I love you all!*

*My deepest gratitude goes for my big family (aunts, uncles, and cousins) for their unwavering love and support. Their presence and encouragement have been the cornerstone of my success.*

*Finally, I would like to extend my sincere gratitude to my close friends who reside in distant corners of the world ‘Lebanon, France, Dubai, Canada, Germany, and America’. Although miles apart, your care packages, video calls, love, moral support, and encouragement have been an invaluable source of strength throughout my academic journey. Your friendship has transcended borders and time zones. Your friendship is a treasure that I will forever hold close to my heart.*

## **Abstract**

On a worldwide scale, breast cancer, glioblastoma, and ovarian cancer present a significant health obstacle, being responsible for cancer-related fatalities. Cancer etiological factors are assorted into genetic or environmental risk factors of which viruses are estimated to contribute to 20% of all cancer cases. Human cytomegalovirus (HCMV) is a herpesvirus that infects a substantial portion of the global population, ranging from 40% to 95%. The variability in the HCMV genome may contribute to its oncomodulatory potential, as it can promote the initiation and dissemination of cancerous cells. Recently, increasing attention has been directed towards the oncogenic role of HCMV, particularly high-risk HCMV strains that can directly induce transformation in primary cells. Polyploid giant cancer cells (PGCCs), have been definitively shown to exhibit cancer stem cells (CSCs) characteristics. These PGCCs give rise to descendant cells through asymmetric division, the latter express markers associated with epithelial-mesenchymal transition (EMT), which in turn promotes invasion and migration. Research indicated that PGCCs generation can be triggered by anti-cancer therapies. PGCCs presence has been particularly linked to cases with poor prognosis, contributing to tumor relapse and resistance to therapy. Previous investigations by our group have highlighted the presence of PGCCs containing HCMV in cancer biopsies, establishing a noteworthy correlation between the presence of PGCCs and HCMV.

HCMV has been implicated in oncogenesis, particularly in breast cancers, glioblastoma (GBM), and epithelial ovarian cancer. Herein, we investigated the oncogenic potential of HCMV in various cancer contexts and explored the molecular mechanisms and transforming capabilities of different HCMV strains isolated from these distinct cancer types and their impact on patient outcomes. To start with breast cancer, we assessed HCMV-B544 and B693 strains, isolated from EZH2HighMycHigh triple-negative breast cancer (TNBC) biopsies. These strains transformed human mammary epithelial cells (HMECs) resulting in CMV-Transformed-HMECs (CTH cells) and PGCCs displaying stemness phenotype. Notably, HCMV persists in long-term cultures, indicating sustained viral replication with alternance of lytic and latent states. In glioblastoma, HCMV was explored as a reprogramming vector, dedifferentiating mature human astrocytes into CMV-Elicited Glioblastoma Cells (CEGBCs) with glioblastoma-like traits. HCMV influences the transformation, invasion, and spheroid formation processes, correlating with increased EZH2 and

Myc expression in GBM biopsies. Eleven clinical HCMV strains isolated from GBM tissues further validated their role in glioblastoma oncogenesis. These CEGBCs exhibit sensitivity to therapeutic interventions, including an EZH2 inhibitor, ganciclovir, and temozolomide triple therapy, offering potential avenues for glioblastoma treatment. In the context of high-grade serous ovarian carcinoma (HGSOC), HCMV-DB and BL high-risk strains transformed ovarian epithelial cells (OECs) into "CMV-transformed Ovarian cells" (CTO). HCMV infection was associated with EZH2 upregulation and the presence of PGCCs with cancer stem cell-like properties expressing EMT markers. From HGSOC biopsies, we isolated three clinical HCMV strains. The high-risk strains transformed OECs resulting in CTO cells that displayed proliferative capacities and revealed an increase in EZH2 levels, along with the generation of PGCCs. Notably, the observed features were curtailed upon the inhibition of EZH2.

All in all, this study emphasizes the diverse oncogenic potential of HCMV in breast cancer, glioblastoma, and ovarian cancer, shedding light on molecular mechanisms, transformation processes, and targeted therapies that may improve the overall survival of cancer patients.

**Keywords :** Human Cytomegalovirus, High-risk strains, oncogenesis, PGCCs, Myc, EZH2, CTH cells, CEGBCs, CTO cells, breast cancer, glioblastoma, high-grade serous ovarian carcinoma.

## Résumé

Le cancer du sein, le glioblastome et le cancer de l'ovaire représentent un problème majeur de santé publique. Les facteurs étiologiques du cancer se répartissent en facteurs de risque génétiques ou environnementaux, parmi ces derniers les virus contribueraient à environ 20% de tous les cas de cancer. Le cytomégalovirus humain (HCMV) est un virus herpès qui infecte une part importante de la population mondiale, avec une prévalence de 40% à 95%. La variabilité génomique du HCMV pourrait contribuer à son potentiel oncomodulateur, car il semble accélérer les mécanismes d'oncogenèse. Les cellules cancéreuses géantes polyploïdes (PGCC) ont des caractéristiques semblables à celles des cellules souches cancéreuses (CSC) et donnent naissance à des cellules « filles » lesquelles expriment des marqueurs associés à la transition épithélio-mésenchymateuse (TEM). La présence de PGCC est particulièrement observée dans les cancers de mauvais pronostic. De précédentes études de notre groupe ont mis en évidence la présence de PGCC infectées par le HCMV dans les biopsies de cancer du sein, évoquant ainsi un rôle oncogène direct du HCMV, notamment de certaines souches virales « à haut risque ». Le HCMV a été suggéré comme participant à l'oncogenèse, en particulier dans les cancers du sein, le glioblastome et le cancer épithélial de l'ovaire. Notre travail de thèse a consisté à examiner le potentiel oncogène du HCMV dans ces cancers. Nous avons évalué les souches virales HCMV-B544 et B693, isolées de biopsies de cancer du sein triple négatif EZH2<sup>High</sup>Myc<sup>High</sup>. Ces souches virales transforment les cellules épithéliales mammaires humaines (HMEC), donnant naissance à « des cellules HMEC transformées par le CMV » (cellules CTH) d'une grande hétérogénéité cellulaire comprenant notamment des PGCC présentant des traits de cellules souches. Une persistance du HCMV est notée dans les cultures à long terme, indiquant une réplication virale continue avec alternance de phase lytique et de latence. Dans le glioblastome, le HCMV a été étudié en tant que vecteur de reprogrammation, dédifférenciant les astrocytes humains matures en « cellules glioblastomateuses induites par le CMV » (cellules CEGBC) présentant des caractéristiques similaires aux cellules de malades. Le HCMV favorise la transformation cellulaire, l'invasion et la de formation de sphéroïdes, corrélé avec une augmentation de l'expression d'EZH2 et de Myc observée également dans les biopsies de glioblastome provenant de malades. Onze souches cliniques de HCMV ont été isolées à partir de biopsies de glioblastome de malades qui reproduisent la transformation

d'astrocytes normaux en cellules glioblastomateuses suite à l'infection virale. Ces cellules CEGBC sont sensibles aux interventions thérapeutiques, notamment à un inhibiteur d'EZH2, au ganciclovir et à une triple thérapie incluant temozolomide-inhibiteur d'EZH2-ganciclovir, offrant ainsi des perspectives nouvelles pour le traitement de ce cancer de très mauvais pronostic. Concernant le cancer séreux épithélial de l'ovaire de haut grade (HGSOC), les souches « à haut risque » HCMV-DB et de BL transforment les cellules épithéliales ovariennes (OEC) en "cellules ovariennes transformées par le CMV" (cellules CTO). Dans ces cellules CTO une augmentation de l'expression d'EZH2 ainsi que la présence de PGCC avec des traits de cellules souches cancéreuses avec TEM ont été observées. À partir de biopsies de HGSOC, nous avons réussi à isoler trois souches cliniques de HCMV qui en infectant les cellules OEC donnent naissance à des cellules CTO hautement prolifératives surexprimant EZH2 et générant des PGCCs ; leur transformation étant réduite par les inhibiteurs d'EZH2 in vitro. En résumé, notre travail met en évidence le potentiel oncogène du HCMV dans trois cancers graves, en dévoilant certains des mécanismes moléculaires mis en œuvre lors de la transformation cellulaire et ouvre la voie à des thérapies ciblées qui pourraient améliorer la survie des patients.

## Chapter 1

### 1 Human Cytomegalovirus (HCMV) in Focus: An Overview of the Virology, Immunology, and Clinical Aspects

#### 1.1 *Herpesviridae* Family and HCMV Discovery

*Herpesviridae* is a family of viruses that includes a large and diverse group of viruses known as herpesviruses. These viruses are characterized by their ability to establish latent infections by remaining dormant within the host's body and reactivate later under certain conditions. Herpesviruses can infect a wide range of species [1,2]. The family *Herpesviridae* is divided into three subfamilies: *Alphaherpesvirinae*, *Betaherpesvirinae*, and *Gammaherpesvirinae*. Each subfamily has distinct characteristics in terms of virus-host interactions, replication strategies, and clinical manifestations. To start with *Alphaherpesvirinae*, these viruses are known for their rapid replication cycle and ability to establish lytic and latent infections, they are often associated with lesions and sores on the skin and mucous membranes. Examples of alphaherpesviruses include Herpes simplex virus 1 (HSV-1), Herpes simplex virus 2 (HSV-2), and Varicella-zoster virus (VZV), which causes chickenpox and shingles. Second, the *Betaherpesvirinae* comprising betaherpesviruses that have a slower replication cycle compared to alphaherpesviruses; they are often associated with persistent infections and can cause long-term health issues. Human Cytomegalovirus (HCMV), also known as Human Herpesvirus 5 (HHV-5), belongs to this subfamily, within the genera *Cytomegalovirus*. On the other hand, we have HHV6A, HHV6B, and HHV7, which belongs to the genera *Roseolovirus*. Third, the *Gammaherpesvirinae* including Gammaherpesviruses that are associated with certain types of cancers, particularly in immunocompromised individuals. Epstein-Barr virus (EBV) or (HHV4), belonging to genera *Lymphocryptovirus*, is associated with infectious mononucleosis and various cancers, and Kaposi's sarcoma-associated herpesvirus (KSHV) or (HHV8), belongs to genera *Rhadinovirus* [1,3]. Both viruses are classified as oncogenic pathogens that infect lymphoblastoid cells such as T or B lymphocytes and establish latency. However, it's worth noting that a lytic infection has also been observed in epithelioid and fibroblastic cells [3].

One of the numerous breakthroughs and advancements documented during the 20th century involved the identification and characterization of HCMV, which stands as one of the most

prevalent viruses and opportunistic pathogens encountered worldwide. Within this discovery, several specific dates stand out [4,5]. In 1881, the German pathologist Ribbert documented the presence of cells containing inclusions in the kidney of a stillborn infant affected by syphilis and in the parotid gland of an infant. These same "protozoan-like" cells were also observed by Jesionek and Kiolemenoglou in 1904 in the lungs, kidneys, and liver of an 8-month-old fetus with syphilis and by Löwenstein in 1907. These cells, characterized by their large eccentrically placed nuclei, appear to represent the earliest descriptions of typical cytomegalic cells, which were later termed 'cytomegalia' in 1907 [6]. In 1921, Goodpasture and Talbert first suggested a definitive connection between viral diseases and cells exhibiting characteristic intranuclear inclusion bodies. This concept was further elucidated by Wyatt et al., who later in 1932 referred to it as "generalized cytomegalic inclusion disease (CID)." This notion was in alignment with the observations and hypotheses put by other researchers, such as Von Glahn, Pappenheimer, Minder, and others. Significantly, the mid-1950s saw a breakthrough with the advent of human cell culture techniques, enabling the isolation of a virus that was later identified as cytomegalovirus [6]. This achievement was the result of independent efforts by three different laboratories: Smith in 1956, Rowe and colleagues in 1956, and Weller and colleagues in 1957. It was subsequently named 'cytomegalovirus' (CMV) [7,8]. This marked a significant milestone in advancing our comprehension of various aspects of the virus, including but not limited to epidemiology, structure, life cycle, replication, latency, pathogenesis, and treatment modalities. These advancements were greatly facilitated by the development of animal models for studying CMV's pathogenesis [9].

## 1.2 HCMV Genome

HCMV stands out as having the largest genome among human herpesviruses, spanning a length of 235 kilobases (kb) [10]. This genome comprises a linear double-stranded DNA (dsDNA) helix, with more than 751 translated open reading frames (ORFs) [11,12]. Furthermore, HCMV produces polyadenylated non-coding RNAs, including four notable long non-coding RNAs (lncRNAs), notably RNA2.7, RNA1.2, RNA4.9, and RNA5.0 [13]. Additionally, it generates non-polyadenylated RNAs, such as microRNAs, which play pivotal roles in various processes like regulating host cell metabolism, immune evasion, and the maintenance of latency [14]. The genome of HCMV is highly complex and encodes a wide range of proteins involved in various

aspects of the virus's life cycle, including replication, immune evasion, and pathogenesis. The organization of the HCMV genome adheres to the characteristic architecture of herpesviruses classified under class E [15]. HCMV genome features two inverted domains: the unique long (UL) and unique short (US) domains, each flanked by a pair of inverted repeats, one at the terminal end (terminal repeat long/internal repeat long (TRL/IRL)) and the other at the junction with the other unique domain (internal repeat short/terminal repeat short (IRS/TRS)). This results in a genome organization denoted as  $TR_L-U_L-IR_L-IR_S-U_S-TR_S$ . Consequently, HCMV gene annotations are based on their respective positions within these genome segments, specifically UL, US, IRL, IRS, TRL, and TRS (**Figure 1**) [16].

**Figure 1: Schematic representations comparing genome organizations.**

Genome organizations of various human herpesviruses including varicella zoster virus (VZV), human simplex virus (HSV), and Epstein-Barr virus (EBV). The labels within each segment of the genome illustrate the following characteristics: terminal repeat long (TRL), unique long (UL), unique short (US), internal repeat long (IRL), internal repeat short (IRS), terminal repeat short (TRS), and internal repeat (IR). Adapted from Crough et al [17].

HCMV displays a remarkably broad tropism, encompassing a diverse range of cell types including epithelial cells, fibroblasts, endothelial cells, monocytes and macrophages, dendritic cells, smooth muscle cells, neural cells, and placental cells [18]. This trait can significantly impact the pathogenesis of acute HCMV infections in vivo. For instance, infecting epithelial cells facilitates transmission between hosts, while infecting endothelial and hematopoietic cells can support systemic spread within the host. Additionally, infecting ubiquitous cell types, such as fibroblastic and smooth muscle cells, provides a conducive environment for efficient viral proliferation [18,19]. It's worth emphasizing that HCMV tropism varies considerably among different HCMV

strains and is primarily influenced by variations within the UL128-131 gene locus. This region has been associated with viral persistence, reactivation, and the ability to infect different cell types. The resulting genetic differences account for inter-strain variations in viral entry. Notably, the UL128, UL130, and UL131 proteins form complexes with the virion envelope glycoprotein gH/gL, specifically the pentamer gH/gL/UL128-131. This complex is responsible for mediating entry into epithelial and endothelial cells [20,21]. Furthermore, laboratory-adapted strains, such as the widely used reference strain AD169 and other well-known strains like Towne or Davis, have lost substantial DNA fragments within their ULb' region due to extensive passaging in human fibroblast cell cultures. Consequently, these laboratory strains replicate efficiently in fibroblasts but exhibit limited replication in other cell types like endothelial or epithelial cells. This is in contrast to clinical isolates, which replicate less efficiently in cultured cells but demonstrate nearly equivalent replication efficiency in endothelial cells [22–24]. Understanding the role of the UL128-131 gene locus and its impact on viral entry and tropism is essential for unraveling the complex interactions between HCMV and its host. This knowledge has implications for vaccine development and antiviral strategies aimed at targeting specific strains or cell types.

### 1.3 Virion Structure

The HCMV virion structure consists of several components (**Figure 2**) that are orchestrated to ensure successful attachment, entry, and establishment of infection in target cells [25].

**Figure 2: HCMV Virion.**

Double-stranded DNA genome is enclosed within an icosahedral symmetry capsid which is further enveloped by a layer called tegument. Mature virions are enveloped; viral glycoproteins protrusions are found on the envelope surface. This description has been adapted and altered based on Tomtishen's work [24].

### 1.3.1 The Envelope

The HCMV virion is enveloped by a lipid bilayer derived from the host cell membrane during the process of virus assembly and budding. The lipid bilayer is approximately 10 nm thick and contains a minimum of 19 integral membrane proteins that play a crucial role in binding to host cells, facilitating viral entry, and, in some instances, evading the host immune response by sequestering human chemokines [21,26]. Among these proteins, key players in virus entry, cell-to-cell transmission, and virion maturation include viral glycoproteins like gpUL55 (gB), gpUL73 (gN), gpUL74 (gO), gpUL75 (gH), gpUL100 (gM), gpUL115 (gL), and the pentameric complex composed of gL, gH, and UL128-131 [21].

### 1.3.2 The Capsid

Measuring about 100 nm in diameter, the icosahedral HCMV capsid, also known as the nucleocapsid, serves as the innermost core layer of the virion particle. It's a proteinaceous shell that encloses the viral genome. Its primary roles are to safeguard and deliver the genetic material to the

host cell's nucleus. This capsid is constructed from a minimum of five distinct proteins, which are meticulously organized into 162 capsomeres. These five proteins encompass the major capsid protein (UL86), the minor capsid protein (UL85), the smallest capsid protein (UL48-49), the assembly protein comprising fragments of UL80, and the minor capsid binding protein (UL46) [27,28].

### 1.3.3 The Tegument

The tegument layer in the HCMV virion is around 50 nm thick and occupies the space between the lipid envelope and the protein capsid [29]. This layer is characterized by its high protein content, accounting for approximately half of all viral proteins present in an infectious virion. Many of these proteins are phosphorylated. These proteins play crucial roles in various aspects of the viral life cycle, including replication, gene expression regulation, viral particle assembly, immune system evasion, and other essential functions. Beyond viral proteins, the tegument layer also contains approximately 70 cellular proteins, as well as viral and cellular RNAs [30,31].

## 1.4 HCMV Life Cycle

The HCMV life cycle is a complex process involving various stages from viral attachment and entry into host cells to replication, assembly, and release of new virions [32].

### 1.4.1 Attachment and Viral Entry

During the viral entry process, HCMV achieves its tropism by employing cell receptor-mediated endocytosis, which is facilitated by virally encoded glycoproteins binding to specific cellular receptors. This entry mechanism can be delineated into three key stages. Initially, the virus adheres to the host cell's surface by binding to heparan sulfate glycosaminoglycans via the virion glycoprotein B (gB) in conjunction with the glycoprotein M/glycoprotein N complex [33]. Subsequently, there is an interaction with entry receptors located on the host cell membrane, including integrins and epidermal growth factor receptors (EGFRs), both of which bind to gB [34,35]. The third step involves either the internalization of the viral particle or the fusion of the viral envelope with the cell membrane, a process also mediated by gB. In addition to gB, this step may involve the trimeric complex comprised of glycoprotein H, glycoprotein L, and glycoprotein O (gH/gL/gO) in fibroblasts, likely due to interactions with platelet-derived growth factor- $\alpha$

(PDGF- $\alpha$ ). In epithelial and endothelial cells, it may alternatively entail the pentameric complex of glycoproteins gH/gL, in conjunction with UL128-131 [36,37].

#### 1.4.2 Lytic Cycle

Viral tegument proteins that are bound to the capsid engage with the host microtubule machinery, leading to the transportation of viral capsids to the nuclear envelope and subsequently into the nucleus, where the viral DNA is released [38]. Within this context, two crucial players in nucleocapsid translocation, uncoating, and the release of the viral genome are the large tegument protein (product of UL48) and the large tegument protein binding protein (product of UL47) [39,40]. In the nucleus, the processes of viral transcription, genome replication, and encapsidation occur. Lytic replication is a regulated sequence of events, with immediate early genes (IE) being expressed first, followed by early (E) and late genes (L). The IE gene products function as transcription factors and expression regulators for the E and L genes. The E proteins primarily interact with host proteins while also impacting the transcriptional and replication machinery for viral proteins. The L proteins serve primarily as structural components of the virions, and they also encompass proteins crucial for the assembly and release of infectious particles [41–43]. In this intricate process, UL54 (the viral DNA polymerase) and UL70 (DNA primase) play pivotal roles in regulating the replication machinery and ensuring an efficient production of new virus progeny. Additionally, various viral-encoded proteins contribute to the regulation of cell signaling pathways and cellular metabolism, as well as the inhibition of initial steps in the immune response to support viral replication and immune evasion [44–48]. For instance, the viral US3 protein sequesters the major histocompatibility complex (MHC) class I within the endoplasmic reticulum (ER), while the US2 and US11 proteins induce the destruction of class I heavy chains, thereby impeding viral clearance by cytotoxic T lymphocytes (CTL) [49].

The nucleocapsid, containing DNA, assembles within the nucleus and exits into the cytoplasm by inducing changes in nuclear lamina components. This process is facilitated by two highly conserved viral proteins, specifically pUL50 and pUL53 [50]. The assembly and transportation of virions involve the integration of various cellular trafficking pathways such as the hijacking of the endoplasmic reticulum (ER), Golgi apparatus, and endosomal machinery, forming the cytoplasmic

viral assembly complex. It is within this complex that capsids acquire their tegument layer and viral envelope from intracellular vesicles [51]. Subsequently, infectious particles are released either by fusing with the plasma membrane or by causing cell lysis, releasing them into the extracellular space (**Figure 3**) [52]. Beside mature virions, two types of defective particles are also released: dense bodies (DBs) and non-infectious enveloped particles (NIEPs) [53]. DBs are larger and denser than mature virions, ranging in size from approximately 250 to 600 nm in diameter; they contain most of the structural proteins but lack a viral genome, which is normally packed into the protective capsid. NIEPs are similar in size to virions but lack a viral genome [54]. The entire lytic replication cycle for HCMV takes approximately 72 hours before new mature virions are prepared to infect further cells, either through release from the infected cells or via cell-to-cell transmission mechanisms [55].

**Figure 3: HCMV Life cycle.**

The life cycle of HCMV involves a series of steps. Initially, HCMV gains entry into the host cell through the interaction of host receptors with specific viral glycoproteins. Following this, capsid and tegument proteins are liberated into the host cytosol. The capsid then releases the viral genome into the nucleus, initiating the expression of immediate early (IE) genes. These IE proteins, in turn, activate the expression of early (E) genes. Early proteins boost

viral genome replication and the expression of late (L) genes. The L gene expression leads to capsid assembly and the expression of tegument and glycoproteins. The genome loaded capsid exits the nucleus through nuclear egress and associates with the tegument proteins. Subsequently, the capsid acquires a viral envelope by budding into intracellular vesicles. Finally, these enveloped viral particles are released into the extracellular space, completing the HCMV life cycle. Figure has been adapted from Crough et al [17].

### 1.4.3 Latent Cycle

Latency in the context of HCMV infection refers to a dormant phase where the viral genome is retained without active virus replication or the release of infectious viral particles, occasionally interrupted by reactivation events [56]. Multiple latency reservoirs have been identified in the blood and bone marrow including mainly CD34+ hematopoietic progenitor cells and CD14+ monocytes. HCMV reactivation could be triggered by monocytes harboring latent viral genomes differentiating into macrophages or dendritic cells (DCs) [57,58]. During latency, only a limited set of genes are expressed, including genes from the UL133-UL138 locus, UL144, the latent unique nuclear antigen (LUNA), the US28 viral G-coupled receptor and chemokine receptor homologue, the latency-associated viral homolog of IL-10 (LAcmvIL-10) encoded by UL111A, a shorter variant of the UL123-encoded IE1 protein (IE1<sub>4</sub>), a transcript associated with latency originating from a distant promoter within the MIE region, and long non-coding RNAs of 2.7 kb and 4.9 kb [59]. The establishment of HCMV latency is a complex process that involves epigenetic silencing of the viral genome through chromatin remodeling around the viral major immediate early promoter (MIEP) and the presence of latency-associated repressors. Histone methyltransferases (HMTs) and histone deacetylases (HDACs) play roles in maintaining latency [60–62]. Cellular defenses and controls, such as nuclear domain 10 (ND10) structures or promyelocytic leukemia protein (PML) nuclear bodies, also contribute to suppressing viral replication by modifying chromatin around the viral MIEP [63–65]. On the other hand, reactivation involves the transition to lytic replication [66]. Various factors can trigger this switch, including cellular differentiation, stress conditions, and certain drugs like histone deacetylase inhibitors; the latter have been shown to alleviate the repressive marks on chromatin, resulting in IE gene expression [67]. Reactivation of latent HCMV can have significant clinical consequences, ranging from severe inflammatory conditions in immunocompromised patients to complications like allograft rejection and graft-versus-host disease in transplant recipients [68,69].

## 1.5 HCMV Prevalence and Spread

HCMV is widely recognized as a ubiquitous virus, with seroprevalence rates ranging from 40% to 90% in the adult population [70]. HCMV infection is considered endemic and doesn't exhibit seasonal variations [71]. The prevalence of HCMV infection varies depending on geographic and socioeconomic factors. In developing regions, more than 90% of preschool children are found to have acquired HCMV during early childhood. In contrast, in industrialized countries, less than 20% of children are seropositive [72,73]. As individuals age, the percentage of seropositive individuals continues to rise, reaching levels between 40% and 70% [74].

The transmission of HCMV is influenced by a multitude of potential sources of exposure [75]. The primary route for acquiring HCMV is the direct contact with body fluids from an infected individual. These fluids encompass saliva, oropharyngeal secretions, urine, cervical and vaginal secretions, semen, breast milk, allografts, and blood products from donors who are seropositive [74]. Another means of contracting the virus is through perinatal or vertical transmission, where HCMV is transmitted through the placenta, a condition known as congenital infection. It's important to mention that infected infants typically excrete substantial amounts of the virus for months to years following infection, as do older children and adults following a primary HCMV infection [76].

## 1.6 Clinical Aspects of HCMV and HCMV-Related Diseases

HCMV infection is mostly asymptomatic yet it can result in a mild illness in immunocompetent individuals. Primary HCMV infection can occasionally lead to a mild syndrome resembling mononucleosis [77]. On the contrary, severe CMV disease occurs in individuals with immature, suppressed, or compromised immune systems, such as neonates, transplant recipients receiving immunosuppressive drugs, and patients with AIDS. This severe form of the disease can have life-threatening consequences or cause significant long-term complications [78]. These complications encompass a wide range of potential clinical manifestations due to the virus's ability to spread through the bloodstream and infect various tissues. This includes gastrointestinal issues, respiratory problems, hematological abnormalities, cardiovascular complications, neurological symptoms, and urological manifestations. Additionally, severe HCMV infection can indirectly

lead to atherosclerosis acceleration, graft rejection, and increased susceptibility to opportunistic infections [17]. In cases of congenital HCMV infection, approximately 90% of infected infants show no symptoms at birth, although about 5% of them may develop complications later in life [79]. Common initial symptoms include jaundice, petechiae, and hepatosplenomegaly [80]. Major long-term complications of congenital HCMV infection encompass prematurity, restricted intrauterine growth, hypotonia, poor feeding, cerebral ventriculomegaly, microcephaly, intracranial periventricular calcifications, sensorineural hearing loss, and, in 10 to 20% of affected infants, chorioretinitis and mental retardation [81,82].

## 1.7 HCMV Detection and Diagnosis

Numerous diagnostic approaches are accessible for detecting HCMV infection, primarily encompassing serological testing, virus culture, identification of viral antigens, and CMV DNA detection through polymerase chain reaction (PCR) [83].

### 1.7.1 Serology

This method relies on assessing the levels of IgM and IgG antibodies in the serum or plasma of patients. The enzyme-linked immunosorbent assay (ELISA) is the most commonly employed technique. The presence or absence of CMV IgG serves as a marker to identify whether the individual has previously experienced a CMV infection. Meanwhile, the detection of IgM antibodies has been employed as an indicator of a recent, acute infection, or viral reactivation [81,84]. Furthermore, by determining the avidity of IgG antibodies, it will be possible to differentiate between an early primary infection (low avidity) and a latter infection (high avidity) during pregnancy [85].

### 1.7.2 Virus Culture

The conventional method for detecting HCMV is through traditional cell culture. In this approach, clinical samples are introduced to human fibroblast cells (MRC5 cells), and their development is observed over a period ranging from 2 to 21 days. The presence of cytopathic effects (CPE), characterized by clusters of flattened and swollen cells, is then directly correlated with the virus's titer. However, the limitation of this method is the extended time required, with results often taking 2 to 3 weeks. To expedite this process, an alternative approach involves the detection of viral

antigens using monoclonal antibodies directed against CMV immediate-early viral antigens via indirect immunofluorescence after a 16-hour incubation period [86,87].

### 1.7.3 Identification of Viral Antigens

This assay relies on the detection of the viral pp65 antigen within blood specimens, specifically within leukocytes, as this antigen is expressed in these cells during the early stages of the HCMV replication cycle [88]. An immunofluorescence assay that identifies pp65 in a sample of peripheral blood leukocytes not only allows for the quantification of positive leukocyte nuclei but also closely correlates with viremia and the severity of clinical disease in immunosuppressed populations [89]. However, a significant limitation of this technique is its lack of automation, requiring skilled individuals for accurate test execution and result interpretation. Furthermore, results should be assessed within a 6-hour window, as delays in processing can significantly reduce the assay's sensitivity, potentially leading to false-negative results, especially in patients with neutropenia [90,91].

### 1.7.4 PCR Amplification

PCR is a widely accessible, rapid, sensitive and specific method for detecting HCMV in various types of samples, including blood, leukocytes, plasma, tissue biopsy specimens, and fluids for instance urine, bronchoalveolar lavage, or cerebrospinal fluid [92]. PCR for HCMV DNA can be conducted in either a qualitative or quantitative manner (Real-Time PCR), enabling continuous monitoring of immunocompromised individuals to identify those at risk for HCMV-related diseases, implement preemptive therapy, and assess treatment response [93]. Additionally, the detection of viral mRNA transcripts in peripheral blood leukocytes can be accomplished through reverse transcriptase PCR (RT-PCR) during active HCMV infection. However, it's worth noting that this method is less sensitive than the pp65 antigen test and PCR in diagnosing HCMV-related diseases [94].

## 1.8 Therapeutic Approaches for HCMV Infection

Effective management of HCMV infection is particularly important for immunocompromised individuals, such as transplant recipients and people with HIV/AIDS, as well as newborns infected with HCMV [95]. Below are the approved therapies for HCMV, their mechanism of action, and

their associated benefits and potential adverse effects in addition to the ongoing research and emerging therapies that hold promise for improving the therapeutic strategies against HCMV infection, offering better patient outcomes [96].

### 1.8.1 HCMV Antivirals

Most of the current FDA-approved drugs for treatment of HCMV, including ganciclovir, valganciclovir, foscarnet, cidofovir, letermovir, and Maribavir target late stages of the virus life cycle including viral replication and DNA packaging with varying efficacy and dose-related cytotoxicity [97].

1.8.1.1 Ganciclovir (GCV) is a nucleoside analogue commonly used to treat HCMV infections, especially in immunocompromised individuals [98]. GCV and its valine ester derivative, valganciclovir (VGCV), are primary treatments for CMV disease. GCV is phosphorylated by the HCMV kinase pUL97 to create ganciclovir monophosphate, which accumulates in infected cells, inhibiting viral DNA replication. While GCV can add one more base to the DNA chain, it triggers nucleotide removal downstream, preventing further elongation. GCV selectively targets infected cells due to its activation by a viral kinase and superior inhibition of viral DNA polymerase over cellular DNA polymerase. Resistance usually arises from UL97 and UL54 mutations. VGCV improves GCV absorption but can lead to adverse effects like neutropenia and nephrotoxicity. VGCV has received approval for use in both the initiation and maintenance treatment of AIDS-related HCMV retinitis. It is also administered for the prevention of HCMV infection and related complications in individuals who have undergone kidney, pancreas, or heart transplantation [99,100].

1.8.1.2 In case of GCV resistance, Foscarnet (FOS), a pyrophosphate analogue, can be used for the treatment of HCMV infections. FOS represents the second medication authorized for addressing HCMV retinitis in AIDS patients. It acts by inhibiting viral DNA polymerase. Unlike some other drugs, FOS doesn't rely on viral kinase-mediated intracellular phosphorylation to exert its antiviral effects, nor does it become incorporated into the developing viral DNA chain. This unique feature positions it as the preferred rescue therapy for patients encountering treatment challenges due to GCV-resistant HCMV strains or those experiencing GCV-induced neutropenia

or leucopenia. However, FOS does come with potential adverse effects including nephrotoxicity as well as hypocalcemia, hypomagnesemia, and hypokalemia, which could be associated with seizures [101,102].

1.8.1.3 Cidofovir (CDV) is a second-line treatments for GCV and FOS-resistant cases. CDV is classified as an acyclic nucleoside phosphonate analogue. Its primary indication is for treating HCMV retinitis in AIDS patients. It is formulated for intravenous use because of its limited oral bioavailability. Additionally, CDV is recognized for its extended intracellular half-life, enabling less frequent drug administration. This characteristic can be advantageous for patients who may have difficulty adhering to daily intravenous dosing schedules. However, CDV is nephrotoxic and causes neutropenia, metabolic acidosis and ocular hypotony [96,103].

1.8.1.4 Letermovir is effective in preventing or treating HCMV infections in recipients of hematopoietic stem cells, thoracic organs, and lung transplants. It offers several advantages over traditional antiviral drugs. Notably, it has a low level of toxicity and excellent oral bioavailability, preventing the urge for hospitalization or intravenous administration. Moreover, letermovir operates by targeting the viral terminase complex and interfering with the viral UL56 gene product, instead of DNA polymerase. This unique mechanism of action reduces the risk of cross-resistance with anti-CMV medications [104,105].

1.8.1.5 Maribavir was being studied for the treatment of resistant or refractory HCMV infections in transplant recipients. It has shown encouraging outcomes in clinical trials. This medication functions by competing with ATP to attach itself to the viral kinase pUL97. Interestingly, Maribavir retains its effectiveness against certain HCMV strains that have developed resistance to GCV, despite the fact that most GCV-resistant strains possess mutations in the UL97 gene. It's important to emphasize that Maribavir cannot be employed concurrently with GCV treatment, as it would impede the initial phosphorylation and activation process of GCV. MBV showed reduced haematotoxicity and nephrotoxicity compared to GCV and VGCV [106,107].

## 1.8.2 Immunotherapy

With the advancement of immunotherapy, a growing cohort of scientists has been exploring its application in the context of HCMV infection.

### 1.8.2.1 Vaccines

Vaccination against HCMV infection remains high priority. In recent years, there has been significant interest among pharmaceutical researchers in developing an effective and safe HCMV vaccine, as immunity can lessen the severity of the disease. Researchers have explored various types of HCMV vaccines, including live vaccines (such as live-attenuated and chimeric viral vaccines) and non-living vaccines (including subunit, RNA-based, virus-like particle, and plasmid-based DNA vaccines) [108,109]. While clinical trials have yielded promising data, it's important to note that an approved HCMV vaccine has not yet been authorized for use. Designing a vaccine for HCMV presents unique challenges. First, the virus can establish lifelong latency in the host after a subclinical primary infection and can spread from cell to cell, evading antibodies in extracellular fluids. Additionally, HCMV can reactivate when the host's immune defenses are weakened. Another obstacle is the diversity of HCMV strains, as the virus frequently undergoes recombination with disruptive mutations identified in clinical isolates, even exhibiting rapid evolution within the host [110]. In summary, the development of an effective HCMV vaccine has been hindered by these complex challenges, despite the pressing need for such a vaccine.

### 1.8.2.2 Antibody Therapy

The FDA has granted approval for passive immunization using HCMV immunoglobulin as a prophylactic measure. This is typically administered alongside GCV, especially in high-risk recipients of lung and cardiothoracic transplants. It is also considered in cases of GCV resistance or poor tolerance. However, when it comes to congenital HCMV, passive immunization with HCMV immunoglobulin has not shown significant reductions in congenital HCMV disease [111]. Therefore, it is not recommended for use in pregnant women with primary HCMV infection.

### 1.8.2.3 Adoptive Cell Therapy (ACT)

T cells isolated from healthy donors who have previously been exposed to HCMV can be expanded in vitro and transferred to immunocompromised patients. These "donor-derived" T cells can help control HCMV reactivation. ACT is now being used as a treatment approach for HCMV reactivation in patients who have undergone allogeneic hematopoietic stem cell transplantation (HSCT) and solid organ transplantation (SOT). Research has demonstrated that autologous

HCMV-specific T cells can directly eliminate primary glioblastoma (GBM) cells. Some researchers have even devised an innovative adoptive immunotherapy approach targeting CMV antigens for patients with recurrent GBM. Experimental results from this approach have shown it to be both safe and linked to extended progression-free survival in 4 out of 10 patients [112].

#### 1.8.2.4 Checkpoint Blockade Therapy

Research has shown that the use of immune checkpoint inhibitors (ICIs) can potentially revive immune function and elicit an immune response to CMV antigens even when in a latent state. One promising approach involves a vector called pS-CIFT-aPD-1, which is designed to express the gene for an antibody targeting the programmed cell death protein 1 (anti-PD-1) [112].

#### 1.8.2.5 Novel US28-targeting Strategies

In search of innovative treatments against HCMV infection, a recent approach has emerged focusing on the role of the surface protein US28, which plays a crucial part during both lytic and latent infections. The methods for therapeutically targeting US28 can be broadly categorized into three distinct categories: small molecules, single-domain antibodies (referred to as nanobodies), and fusion toxin proteins (FTPs) [112,113].

## Chapter 2

### 2. HCMV-Induced Polyploid Giant Cancer Cells and Their Significance in Tumorigenesis

#### 2.1 Morphological Characteristics of PGCCs

Polyploid giant cancer cells (PGCCs) are characterized as either gigantic mononuclear cells with multiple genome copies or multinuclear cells [114]. According to the definition by Zhang et al., a PGCC is delineated as a cell three times larger than a typical diploid cancer cell. However, the size of a PGCC can vary significantly depending on the DNA content and the number of nuclei within the cells, sometimes reaching dimensions that are 10 to 20 times larger than a regular diploid cell [115]. PGCCs have a slow cell cycle and divide through asymmetric cell division patterns, which include budding and bursting. Budding is characterized by the release of numerous small daughter cells resembling the growth and division mechanisms seen in simpler organisms like yeasts. Additionally, dormant PGCCs are associated with the induction of quiescence and increased storage capacity through the presence of vacuoles and accumulation of lipid droplets, increased metabolic capacity, and elevated energy production [116–118].

#### 2.2 PGCCs Stimuli and Mechanisms of Generation

PGCCs frequently emerge as a result of various stressors, such as exposure to chemotherapy, ionizing radiation, conditions of hypoxia, viruses, and other stimuli that lead to DNA double-strand breaks (**Figure 4**). CoCl<sub>2</sub> serves as a mimic for hypoxia-induced cellular responses in vitro and activates signaling pathways associated with hypoxia. CoCl<sub>2</sub> plays a role in stabilizing hypoxia-inducible factor (HIF)-1 $\alpha$  by inhibiting proline hydroxylase. Additionally, chemotherapy drugs like capecitabine, oxaliplatin, and irinotecan, as well as radiation therapy, can induce PGCCs formation. Tumor tissues rich in PGCCs are associated with higher risks of recurrence, metastasis, chemoresistance, and poor prognosis [119,120].

The generation of PGCCs involves a complex interplay of cellular processes and signaling pathways. The giant cell cycle, which leads to the formation of PGCCs, differs from the regular cell cycle in certain aspects. While the exact mechanisms can vary between different types of cancer, here are some general insights into how PGCCs are generated and the characteristics of

the giant cell cycle (**Figure 5**). PGCCs formation can occur through various mechanisms, including endoreplication, mitotic slippage, cytokinesis failure, cell fusion, or cell cannibalism with the former being the predominant mechanism. While studies have documented the occurrence of PGCCs resulting from cell fusion in Hodgkin's lymphoma and glioblastoma cell lines, it's worth noting that, in MDA-MB-231 and ovarian cancer cells, cell fusion contributes to only a modest fraction, ranging from 10% to 20%, of all PGCCs [119,121].

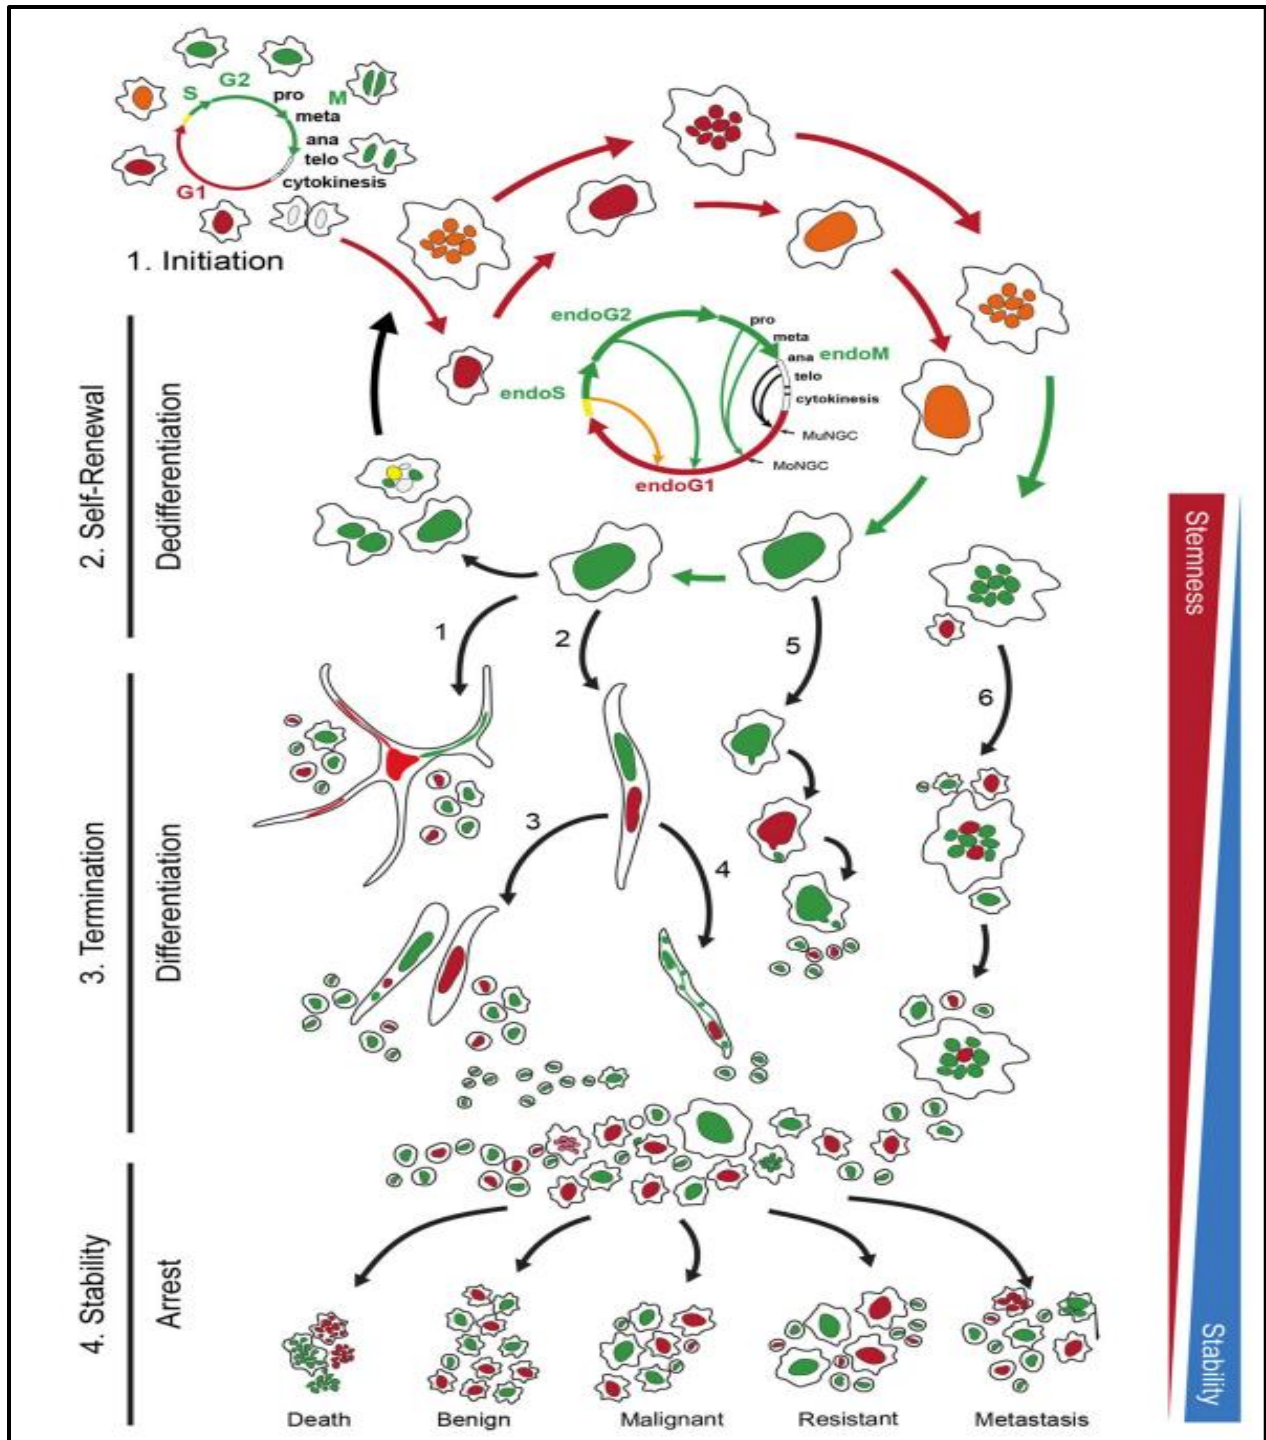

**Figure 4: Scheme illustrating PGCCs formation mechanisms.**

PGCCs formed through endoreplication and cell fusion have developed the capacity to undergo division using mechanisms similar to those seen in single-celled organisms, such as budding and viral-like amitotic division, which leads to the production of tumor-initiating cells. Adapted from Chen et al. [120].

### 2.3 Characteristics of PGCCs and Potential Biomarkers

PGCCs exhibit a unique combination of markers, encompassing both normal and cancer stem cell (CSC) indicators [115,119]. These markers include OCT4, NANOG, SOX2, CD44, and CD133. Notably, the daughter cells originating from PGCCs also display characteristics similar to stem cells and continue to express CSC markers, specifically the surface glycoproteins CD44 and

CD133. PGCCs maintain a highly dedifferentiated state, reminiscent of embryonic cells, and possess more pluripotency compared to typical CSCs. Furthermore, these PGCC progeny share similarities with blastomeres observed during embryonic development, possessing the capability to differentiate into various cell types representing the three germ layers: ectoderm, mesoderm, and endoderm, as demonstrated *in vitro*. Their expression profile includes spatiotemporal markers associated with embryonic development and self-renewal, such as NANOG, OCT3, OCT4, aldehyde dehydrogenase-1A (ALDH1A), and SOX-2. These daughter cells exhibit the potential to differentiate into diverse benign cell types, such as adipocytes, chondrocytes, erythrocytes, and osteocytes, or give rise to carcinomas with differing grades [119]. In a study by Zhang and colleagues, PGCCs progeny derived from the MCF-7 cell line were observed to differentiate into benign stromal cells, including myoepithelial, endothelial, and erythroid cells. Considering the role of the tumor stroma in modulating drug bioavailability and enzymatic degradation, PGCCs can exert a significant influence on promoting resistance to various anticancer therapies [115]. Further, PGCCs and their progeny often undergo epithelial-mesenchymal transition (EMT). EMT involves significant cytoskeletal transformations that lead to alterations in cell adhesion and morphology, playing a critical role in the metastatic dissemination of cancer cells. PGCCs, along with their progeny, have been observed to exhibit distinct expression patterns, characterized by elevated levels of mesenchymal markers like vimentin, fibronectin, and N-cadherin, accompanied by reduced levels of epithelial markers such as cytokeratin and E-cadherin. This pattern mirrors the connection often seen in cancer cells, where EMT and the acquisition of stem cell-like features are closely intertwined. Likewise, in PGCC progeny cells, there is a notable association between the expression of EMT markers and stemness markers. This association is exemplified by the induction of EMT in human mammary epithelial cells triggered by transforming growth factor- $\beta$  (TGF- $\beta$ ), which also facilitates the generation of cells exhibiting stem cell-like properties, such as CD44 expression and self-renewal capacity [119,122].

**Figure 5: A scheme illustrating the giant cell cycle.**

The giant cell cycle closely mimics the division of blastomeres. Upon initiation by either intrinsic genetic factors or external stresses, a somatic cell enters a phase of self-renewal endoreplication and initiates dedifferentiation or

reprogramming. Subsequently, the reprogrammed cell enters a termination phase to start differentiation. During this phase, giant cells employ multiple primitive cell division mechanisms to generate diploid daughter cells. These include (1) horizontal genetic transfer, where DNA migrates horizontally into adjacent cells through cytoplasmic extensions followed by budding, (2) the formation of elongated cells with two giant nuclei, as well as (3) splitting in the middle of the giant cell or (4) direct budding from both (5) mononucleated and (6) multinucleated giant cells. In the stability phase, differentiated cells gradually organize themselves out of chaos, reaching a specific developmental level. Dominant clones emerge from this chaos, resulting in the formation of a visible tumor which can behave as benign, malignant, resistant, metastasis or death. Cells that immediately bud off from the giant cells exhibit a high level of stemness, symbolized by a red triangle, and progressively attain stability during the process of differentiation, represented by a blue triangle. Adapted from Liu et al [122].

#### 2.4 Potential Involvement of PGCCs in Cancer Progression

Accumulating evidence underscores the significance of genome duplication, or polyploidization, as a fundamental genetic trait in cancer [114,118,121]. Recently, polyploidy was found to be present in approximately 37% of human tumors [123,124]. Polyploidization is recognized for its role in promoting chromosomal instability, primarily through the frequent missegregation of chromosomes during cell proliferation, and by creating conditions conducive to aneuploidy [123]. This, in turn, fosters cancer evolution by introducing genetic diversity. PGCCs have been described in a broad spectrum of high-grade and chemoresistant tumors, as well as in various cancer cell lines [114,119]. These encompass breast and colorectal cancer, glioma, lung, prostate, ovarian, cervical, lymphoma, nasopharyngeal, pancreatic carcinoma, neuroblastoma, renal, thyroid, bowel sarcoma, and melanoma [114,125,126]. It's worth noting that the presence of PGCCs has been preferentially reported in poor prognosis cancers participating in tumor relapse and therapy resistance. PGCCs play a role in contributing to the heterogeneity of tumors (**Figure 6**) and have been identified in well-established cancer cell lines, including MDA-MB231, MCF-7, U87MG, SKOV-3, HeLa, A549, PC-3, SW620, and HCT-116 cell lines [119]. Thus, discovering distinctive traits that symbolize polyploid tumors has the potential to enhance the clinical management and classification of tumors based on their ploidy status.

**Figure 6: Generation of PGCCs in various cancer types.**

Representative images of PGCCs in (A) breast cancer tissues, (B) WHO grade II gliomas where the black arrow points a single PGCC, and the black frame shows a PGCC with single giant-nucleus as well as in WHO grade IV gliomas where the black arrow points a single PGCC, and the lower black frame shows a PGCC with multi-nucleus, (C) high grade ovarian serous carcinoma, and (D) colorectal cancers. Adapted and modified from several studies considering the link between PGCCs and cancer [120,126–128].

## 2.5 PGCCs and Oncoviruses

Since its inception, the field of viral oncogenesis has yielded groundbreaking insights into the origins of human cancer, illuminating the intricate molecular mechanisms and multifaceted interactions between the host and oncogenic viruses. Approximately 15 to 20% of human cancers worldwide can be attributed to infections caused by oncoviruses. These oncoviruses include human papillomaviruses (HPV), Epstein-Barr virus (EBV), hepatitis B and C viruses (HBV, HCV, respectively), human T-cell lymphotropic virus-1 (HTLV-1), Kaposi's sarcoma herpesvirus (KSHV), and Merkle Polyomavirus (MCPyV) (**Table 1**) [127]. Although significant advancements have expanded our understanding of how these pathogens designate cellular machinery to establish infection and initiate common pathways leading to tumorigenesis, as well as to replicate and maintain persistence, the development of targeted therapies and definitive curative clinical treatments remains a formidable challenge. This challenge primarily stems from the limitations of equivalent animal models and the mysterious nature of certain mechanistic

aspects involved in cancer induction by these agents, given their diverse characteristics. Nonetheless, polyploidy emerges as a pivotal common trait shared among oncoviruses, where distinct viral proteins can act as catalysts for the induction of polyploidy. Polyploidy is increasingly recognized as an initial trigger for cellular transformation within this context [128–130].

### 2.5.1 HPV

HPV, a small double-stranded circular DNA virus belonging to the Papillomaviridae family, encompasses more than 200 identified types categorized by tissue tropism (skin or mucosa) and malignant transformation potential (high risk and low risk). Low-risk (LR) HPVs cause benign warts, while high-risk (HR) HPVs are associated with high-grade cervical lesions and cancers, particularly HPV-16 and -18 [131,132]. The oncogenic potential of HR-HPVs is primarily attributed to the HPV-E6 and -E7 proteins [133]. Polyploidy is commonly observed in the context of HPV infection, particularly in cervical carcinogenesis. Tetraploidy is an early event, and tetrasomy is detected in cervical squamous intraepithelial lesions caused by HR-HPVs [134,135]. Additionally, polyploidy is linked to high-grade squamous intraepithelial lesions (HGSIL) [136,137]. The expression of E6 and E7 oncoproteins is associated with a higher proportion of cells with  $>4N$  DNA content [138]. The mechanisms behind HPV-induced polyploidy are diverse. E6 and E7 can induce abnormal centrosome duplication and erroneous mitotic spindle pole formation, decoupling centrosome duplication from cell cycle division and causing genomic instability [139]. Furthermore, E6 disrupts the mitotic checkpoint by interfering with p53-mediated functions, while E7 overcomes the mitotic checkpoint through a p53-independent mechanism, possibly by modulating Rb function [140]. Further, E6 and E7 downregulate nuclear p21 localization and upregulate cyclin-dependent kinase 1 (CDK1) upon microtubule disruption, contributing to postmitotic checkpoint abrogation-induced polyploidy [141]. This effect is also observed with E7 through its role in Rb downregulation [142]. Simultaneous expression of E6 and E7 induces polyploidy by disrupting the spindle checkpoint and upregulating G2-M proteins. Endoreplication, characterized by multiple S phases without mitosis, is associated with HPV-16 E5 and E6 oncoproteins, leading to enlarged nuclei and increased cellular DNA content [143,144]. Multinucleated cells with enlarged nuclei result from two consecutive S phases without cytokinesis upon HPV-18 E7 transduction [145]. Re-replication is induced by HPV-16 E7 in response to DNA

damage, mediated by the DNA replication initiation factor [146,147]. E6 and E7 enhance HIF protein accumulation and activity in human cervical cancers [148]. In summary, HPV oncoproteins, particularly E6 and E7, employ various mechanisms to induce polyploidy, contributing to cervical carcinogenesis. These mechanisms encompass centrosome abnormalities, mitotic checkpoint abrogation, endoreplication, multinucleation, and re-replication, with downstream effects on genomic stability and cellular transformation. Additionally, HPV infection is associated with increased HIF activity in cervical cancers.

### 2.5.2 EBV

EBV, a member of the Herpesviridae family within the Gammaherpesvirinae subfamily, is a linear, double-stranded DNA virus [149]. It is the first isolated tumor virus and primarily infects B lymphocytes [150]. EBV is associated with a variety of malignancies, including lymphomas such as Hodgkin's lymphoma, diffuse large B-cell lymphoma, and Burkitt's lymphoma, as well as carcinomas like gastric and nasopharyngeal carcinoma (NPC) [150]. Several viral latent antigens, including Epstein–Barr virus nuclear antigen 1 (EBNA1), EBNA2, EBNA3, and the latent membrane protein 1 (LMP1), play essential roles in B-cell transformation [151]. In tissue biopsies of NPC, polynuclear giant cancer cells are observed, often surrounded by small nucleus-containing bodies indicative of budding cells [152]. Multinucleated giant cells are also formed following EBV replication in epithelial NPC hybrid cells [153]. EBV-infected nasal mucosal neoplasms display cells with increased volume and pronounced multinucleation, some containing over 12 nuclei [154]. Chromosomal integration of the viral genome into primary human B cells has been linked to polyploidy [155]. Infection of B cells with an EBV strain isolated from nasopharyngeal carcinoma predisposes them to polyploidy, with cells exhibiting multiple micronuclei or a single large polyploid nucleus [156]. Multinucleation and micronucleus formation have been detected in human laryngeal carcinoma Hep-2 and osteosarcoma U-2 OS cells following EBNA2 expression [157]. Stable expression of LMP1 in Burkitt's lymphoma cell lines is associated with multinuclearity, indicating a close correlation between polyploidy and EBV infection or the expression of EBV-latent oncoproteins [158]. Additionally, EBV latent genes compromise the mitotic spindle assembly checkpoint, preventing metaphase arrest [159]. Cell cycle progression without cytokinesis, G1 checkpoint disruption, and spindle assembly checkpoint disruption can

lead to polyploidy upon EBNA3C or EBNA2 expression [157]. Expression of EBNA2 or LMP1 triggers cell re-entry into S phase. EBNA-1, EBNA-3, and EBNA-5 expression enhances the synthesis, transcription, and stability of HIF-1 $\alpha$ , respectively [160,161]. In terms of telomere dysfunction, LMP1 expression is associated with an increase in telomeric aggregates, a decrease in total telomere number, an increase in multinucleated cells, and an increase in nuclear volume. In brief, EBV infection and the expression of EBV-latent oncoproteins are closely linked to polyploidy, which can occur through various mechanisms, including disruption of cell cycle checkpoints, centrosome abnormalities, and telomere dysfunction [162,163]. These interactions contribute to the oncogenic potential of EBV in various malignancies.

### 2.5.3 KSHV

Kaposi's sarcoma-associated herpesvirus (KSHV), also known as human herpesvirus 8 (HHV-8), is a double-stranded DNA gamma-herpesvirus capable of infecting various cell types, including monocytes, dendritic cells, keratinocytes, B lymphocytes, oral epithelial cells, and endothelial cells [164]. It exists in both lytic and latent forms and is responsible for several malignancies, including Kaposi sarcoma (KS), primary effusion lymphoma, multicentric Castleman disease, and plasmablastic lymphoma [165]. KSHV encodes several viral oncogenes, such as latency-associated nuclear antigen (LANA), K cyclin, and viral FLICE-inhibitory protein (vFLIP), which play roles in inactivating tumor suppressor pathways, promoting cell cycle progression and DNA replication, as well as activating nuclear factor kappa B (NF $\kappa$ B) to support cell survival [166,167]. In terms of polyploidy, KSHV infection induces a multinucleation state characterized by enlarged and irregularly shaped nuclei in various cell types [168]. Constitutive expression of LANA in different cell lines results in a dramatic increase in the multinucleated phenotype, characterized by cells with two or more polarized nuclei. K cyclin expression leads to cells with enlarged nuclei and multiple large multi-lobular nuclei, highlighting a strong association between KSHV and polyploidy. Several mechanisms contribute to KSHV-induced polyploidy. KSHV can induce abnormal centrosome duplication and multipolar or monopolar spindle formation, mediated by LANA and K cyclin proteins. Aurora kinase B cleavage by serine protease-N terminus in KSHV-latently infected tumor cells promotes the transition from metaphase to telophase, enhancing mitotic progress and tumorigenesis. LANA induces S-phase entry and multinucleation by

protecting cells from cell cycle arrest; it also interacts with the spindle checkpoint protein Bub1, leading to Bub1 ubiquitination and degradation, favoring multinucleation. K cyclin expression results in DNA replication and cell nuclei division without simultaneous cell division [169,170]. Hypoxia, a condition of reduced oxygen availability, is linked to KSHV-induced polyploidy. KSHV viral interferon regulatory factor 3 (vIRF-3) interacts with and enhances the activity of HIF-1 $\alpha$ , leading to increased angiogenesis through vascular endothelial growth factor (VEGF) activation [171]. Regarding senescence, viral v-cyclin protein induces senescence during latent infection by disrupting the cell cycle and activating the DNA damage response. However, viral FLICE inhibitory protein (v-FLIP) can bypass senescence, allowing the growth and division of latently infected cell populations, which may include a subpopulation of polyploid cells [172]. In summary, KSHV is associated with polyploidy through various mechanisms, including centrosome abnormalities, spindle checkpoint disruption, cell cycle deregulation, and interactions with cellular proteins involved in mitosis and senescence. These mechanisms contribute to the complex interplay between KSHV infection and the development of malignancies.

#### 2.5.4 HTLV-1

Human T-cell lymphotropic virus type 1 (HTLV-1), the first human retrovirus discovered, belongs to the Retroviridae family. While it can infect various human cell types in vitro, HTLV-1 primarily undergoes productive replication within CD4<sup>+</sup> T helper cells. HTLV-1 is the causative agent of adult T-cell leukemia/lymphoma (ATL), a highly aggressive non-Hodgkin's peripheral T-cell malignancy. The viral oncoprotein Tax plays a central role in the development of ATL. Tax activates genes that prevent cell death and disrupts the normal cell cycle, leading to DNA damage. This results in the clonal expansion of T cells harboring the HTLV-1 provirus, eventually leading to cellular immortalization and malignant transformation. HTLV-1 infection can lead to the formation of large lymphoma cells, especially in the presence of Tax [173,174]. Specifically, HTLV-1-induced multinucleated giant cells, characterized by giant lobulated nuclei or enlarged nuclei, have been observed in mammalian cells with elevated Tax expression [175–178]. HeLa cells expressing Tax also displayed larger cell sizes and DNA content greater than that of cells lacking Tax expression [179]. HTLV-1-infected CD4<sup>+</sup> cell clones exhibited enlarged, well-separated nuclei in binucleated and multinucleated cells, and this morphological feature correlated

with Tax expression levels [180]. Thus, HTLV-1 plays a significant role in inducing polyploidy, leading to the formation of multinucleated cells and contributing to the pathogenesis of ATL. This occurs through various mechanisms involving disruption of the mitotic checkpoint, alteration of cell cycle regulation, and enhanced HIF-1 $\alpha$  expression.

### 2.5.5 HBV

Hepatitis B virus (HBV), as the prototype member of the Hepadnaviridae family, is an enveloped virus with partly double-stranded DNA. It shares some characteristics with retroviruses, involving the use of reverse transcriptase during its replication cycle [181]. HBV is primarily a hepatotropic virus, with hepatocytes being its major target and the confirmed site for HBV replication. Infection and replication of HBV in the liver can lead to various complications, ranging from acute hepatitis to severe conditions like liver failure and hepatocellular carcinoma (HCC) [182]. In terms of oncogenic proteins, the hepatitis B virus X protein (HBx or pX) plays a significant role in promoting the progression of the cell cycle, inhibits the expression of tumor suppressor genes, including p53, and affects the transcription of methyltransferases [183]. It has been shown that HBx hinders the suppression of E2F1 activity, which is a key promoter of cell cycle progression, through the deactivation of the Rb gene promoter and consequently the tumor suppressor Rb. Furthermore, HBx augments CDK2 activity, resulting in a disruption of the balance between E2F1 and Rb [184]. These functions suggest its potential involvement in the pathogenesis of HCC and cellular transformation [183]. Another oncogenic factor is the HBV large surface protein (LHBs), which exhibits properties that may contribute to hepatocarcinogenesis [185]. Polyploidy, mainly endoreduplication and hyperploidy, have been exclusively identified in peripheral blood cells of individuals with chronic HBV infection when compared to HBV-negative individuals. Nuclear ploidy is positively correlated with poor prognosis and HBV infection [186,187]. Notably, DNA polyploidy is significantly increased in the liver tissues of HCC patients with a history of HBV infection [188]. This observation is consistent with cellular models where HBV-positive hepatoma cell lines exhibit higher levels of hyperploidy than HBV-negative cells [189]. Mechanistically, the expression of HBV pX can lead to the depletion of p53, suggesting an antagonistic relationship between p53 and pX-induced polyploidy [190]. Moreover, both LHBs and pX protein contribute to the override of the G2/M checkpoint. This results in the attenuation of the DNA damage

checkpoint and inhibition of p53-mediated apoptosis. Furthermore, cells expressing HBV LHBs experience cytokinesis failure compared to controls [189]. In HBV pX-induced polyploid cells, DNA re-replication occurs alongside aberrant mitotic spindle formation [191]. This DNA re-replication is associated with the upregulation of Cdt1 and Cdc6, which are essential for pre-replicative complex assembly [190]. Lastly, HBx interferes with the degradation of HIF-1 $\alpha$  protein and enhances its synthesis [192,193]. Hence, HBV, especially through the actions of HBx and LHBs, is strongly linked to the induction of polyploidy, which can contribute to hepatocellular carcinoma development. This occurs through mechanisms involving the disruption of cell cycle checkpoints, cytokinesis failure, DNA re-replication, and interference with HIF-1 $\alpha$  regulation.

#### 2.5.6 HCV

Hepatitis C virus (HCV), a member of the Flaviviridae family, is a small, hepatotropic virus with a single-stranded RNA genome that is enveloped and replicates in the cytoplasm. Various cell types, including dendritic cells, epithelial cells, lymph nodes, and others, can support HCV replication [195]. Similar to HBV, HCV infection can lead to cirrhosis, severe liver disease, and ultimately HCC [194]. There is also a strong potential association between HCV infection and non-Hodgkin's B-cell lymphoma [195]. The development of HCV-mediated HCC is driven by long-standing hepatic inflammation, oxidative stress, and the potential for DNA damage. Additionally, it involves the alteration of normal cellular signaling pathways and the stimulation of host cell growth, potentially mediated by specific HCV proteins, including the core proteins NS3, NS5A, and NS5B [196]. Polyploidy has been observed in the context of HCV infection. In comparison to peripheral blood mononuclear cells (PBMCs) isolated from healthy individuals, PBMCs from HCV-infected patients have been found to exhibit chromosomal polyploidy [197]. Furthermore, primary human and mouse hepatocytes infected with the HCV strain showed a higher frequency of polyploidy compared to non-infected cells. The expression of the viral core protein was found to induce extensive polyploidy in various cell lines, including the human liver cell line HepG2 and the embryonic kidney cell line HEK293. Moreover, it led to a two-fold increase in polyploidy in primary splenocytes, hepatocytes, and embryo fibroblasts isolated from transgenic mice [197]. The HCV core protein appears to trigger polyploidy by upregulating the transcription of HIF-1 $\alpha$  mRNA [198].

### 2.5.7 MCPyV

Merkel cell polyomavirus (MCPyV) belongs to a family of small, non-enveloped, icosahedral viruses with double-stranded DNA. MCPyV stands out as an oncogenic virus known to cause a rare and aggressive skin cancer called Merkel cell carcinoma (MCC) [199,200]. The key players in MCPyV-induced transformation and tumorigenesis are the transforming large T antigen (LTag) and small T antigen (sTag), which interact with important cellular factors disrupting the role of tumor suppressors like Rb and p53, contributing to the development of cancer [201,202]. The expression of MCPyV sTag has been shown to lead to the formation of multinucleated cells and an increase in the population of cells with more than four sets of chromosomes (>4N) in human diploid fibroblastic cells known as WI38 [203]. Moreover, when sTag was induced in C57BL/6 mice, it resulted in the development of poorly differentiated neoplasia. These tumors exhibited pleomorphic nuclei with variations in size and shape, along with multiple nucleoli [204]. This phenomenon is similar to the induction of polyploidy observed in the context of John Cunningham Polyomavirus (JCPyV) and BK Polyomavirus (BKPyV) infections, as well as infection with simian virus 40 (SV40), which is a closely related oncogenic primate virus [124].

**Table 1: Oncoviruses.**

Oncogenic Viruses	Genome	Human Cancers	Mode of infection	Oncoproteins
<b>EBV</b>	dsDNA	Burkitt's lymphoma, Hodgkin's lymphoma, posttransplantation lymphoma, nasopharyngeal carcinoma	Saliva, milk, blood, organ transplantation	EBNA1, EBNA2, EBNA3A, EBNA3B, EBNA3C, LMP1
<b>HBV</b>	dsDNA	Hepatocarcinoma	Transplacentally, milk, sexually, parenteraly, percutaneously	HBx
<b>HCV</b>	ssRNA	Hepatocarcinoma	Injection equipment, blood transfusion, sexually	Core protein
<b>HPV</b>	dsDNA	Cervical cancer, penis cancer, anal cancer, head and neck carcinoma	Sexually	E6, E7

## 2.6 HCMV and PGCCs

In general, oncoviruses employ various mechanisms that can be considered as early events leading to polyploidy, tumor advancement, and diversity within tumors. Interestingly, HCMV shares many of these mechanisms involved in inducing polyploidy [124–126,205]. For example, HCMV infection leads to the generation of excess centrosomes and the formation of abnormal mitotic spindles [205]. Moreover, HCMV proteins interact with the p53 protein, both in vitro and in vivo, resulting in the functional inactivation of p53. Additionally, HCMV affects the Rb protein through the HCMV UL97 protein, leading to Rb inactivation by phosphorylation, and it binds to pp71, which is part of the Rb protein family, ultimately causing their degradation [206,207]. Furthermore, HCMV has been shown to activate Myc at both the transcriptional and translational levels and induce the expression of HIF-1 $\alpha$  [208–210]. HCMV infection also gives rise to multinucleated giant cells through cell fusion and upregulates the expression of G2/M transition regulators, including polo-like kinase 1 (Plk1) [205]. These findings suggest a potential connection between HCMV infection, the induction of polyploidy, and the development of tumors. It's worth noting that there may be a possible link between oncogenic viruses, the presence of a polyploid phenotype, and resistance to therapy, metastasis, and disease recurrence, as discussed in previous reviews [124]. This connection is strengthened by observations that chromosomal alterations coincide with morphological transformation [211], and the multinucleated cell phenotype is triggered by the expression of viral oncoproteins rather than simple cell fusion, a phenomenon also observed with other non-oncogenic pathogens [177,212]. Additionally, the emergence of a blastomere-like cycle with “CMV-transformed HMECs” or CTH cells in HMECs long-term cultures infected with HCMV as well as the detection of polyploidy and oncogenic potential in CTH cells have been previously shown, by our laboratory [125,126]. Several HCMV clinical strains were used to infect Human Mammary Epithelial Cells (HMECs) cultures which were grown for an extended period of time. Cultures of uninfected HMECs were terminated after fifty days

due to cellular senescence, similarly the cultures that became senescent when infected with HCMV-SD, HCMV-FS, HCMV-KM, HCMV-RM, or HCMV-PJ strains. While all clinical isolates could be cultured for about two months in HMECs, only HCMV-BL strain, along with the previously described HCMV-DB, exhibited sustained growth. These cells were termed ‘CMV-transformed HMECs’ or CTH cells. In CTH cultures, several atypical cells with distinct morphologies were observed including giant cells with a blastomere-like appearance, numerous small round daughter cells, a combination of epithelial and mesenchymal cells, filopodia, and patterns indicating asymmetric cell division [125,126]. All of these patterns may represent slow self-renewing cells undergoing various stages of the previously described giant cell cycle. This cycle consists of a series of synchronized events characterized by the emergence and dominance of enlarged giant cells, which then produce multiple small daughter cells. Furthermore, using confocal microscopy, common morphological features of PGCCs, characterized by their large size and giant nuclei, were detected, along with a broad range of cell sizes. Nehme et al. detected polyploidy in cultures infected with HCMV-BL as shown by flow cytometric analysis with propidium iodide staining. A significant percentage of cells with polyploidy, including polyploid giant cells (>4N), as well as other subpopulations like large tetraploid cells (LCs), intermediate cells (ICs), and diploid small cells (SCs) were observed. To assess the transforming potential of immortalized CTH cells, they performed a soft agar colony formation assay, which showed an increase in colony formation in CTH-BL and CTH-DB cells. This was associated with a significant increase in cell proliferation, as evidenced by a seven-fold rise in Ki67 antigen expression, increasing from 6.9% in control cells to 51.5% and 53.9% in CTH-BL and CTH-DB cells, respectively. Among these, PGCCs exhibited the highest level of Ki67 antigen expression [125,126]. Consequently, there is a growing need for novel treatment approaches that not only disrupt the replicative machinery of viral infections and inhibit the immortalizing and transforming capabilities of oncoviruses but also target PGCCs as a therapeutic strategy.

## Chapter 3

### 3. HCMV-Mediated Oncogenesis

#### 3.1 HCMV Prevalence in Diverse Forms of Cancer

While the frequency of HCMV detection remains a subject of debate, several research groups have detected HCMV and linked it to various human malignancies. HCMV-associated nucleic acids and proteins have been found in tumors and peripheral blood of patients with breast cancer, glioblastoma multiforme (GBM), high-grade serous ovarian carcinoma, neuroblastoma, medulloblastomas, colorectal cancer, and prostate cancer. These findings suggest a potential correlation between HCMV and cancer progression, with some studies reporting poorer prognosis in cases with extensive HCMV expression [70,209,213,214]. It has been proposed that HCMV gene products may modulate oncogenesis development and activate transformation-related pathways (**Table 2**). This concept aligns with the idea of oncomodulation, where disturbances in intracellular signaling pathways, transcription factors, and tumor suppressor proteins in the tumor environment create opportunities for HCMV to exert its oncomodulatory effects, potentially enhancing malignancy [215,216]. The variability in detecting HCMV, ranging from no detection to a high percentage of positivity, can be attributed to the specific methods employed for its detection, including IHC, PCR, histopathology, serology, antigenemia, etc.. [217].

### 3.2 HCMV, A Candidate Oncogenic Virus, Fulfilling Cancer Hallmarks

Hanahan and Weinberg updated their framework to include new additional hallmarks, and the list has continued to evolve to reflect our growing knowledge of cancer (**Figure 7**). Originally and in 2000, Douglas Hanahan and Robert Weinberg outlined six key hallmarks of cancer including sustaining proliferative signaling, evading growth suppressors, resisting cell death, enabling replicative immortality, inducing angiogenesis, as well as activating invasion and metastasis [218]. Afterwards, in 2011, they expanded on the initial hallmarks and introduced two additional ones that involves reprogramming of energy metabolism and evading immune destruction [219]. In 2022, Douglas Hanahan further incorporated two hallmarks, tumor-promoting inflammation and genome instability and mutation [220] as depicted in the figure below. HCMV fulfills all the criteria associated with cancer hallmarks, as elaborated in the subsequent discussion below and in **Table 3**.

**Figure 7: The Hallmarks of Cancer.**

The conceptualization of the hallmarks of cancer serves as an exploratory instrument, aiming to simplify the immense complexities of cancer's various phenotypes and genotypes into a working framework of fundamental principles. The hallmarks of cancer graphic has been adapted from Hanahan and Weinberg [218–220].

### 3.2.1 Sustaining Proliferative Signaling

One of the primary characteristics of cancer cells is their capacity for continuous and uncontrolled proliferation, leading to unlimited growth [221]. This phenomenon is primarily achieved through several mechanisms including independent production of growth factors, stimulation of neighboring tumor-associated cells to produce various growth factors that support cancer cells via paracrine signals, and the constant activation of downstream signaling pathways [222]. Notably, certain HCMV proteins, including IE1, IE2, pUL44, and pUL84, have been shown to play a role in regulating the tumor suppressor protein p53 by interacting with it and influencing p53-mediated transcription, thereby exerting control over the cell cycle at various checkpoints [223–225]. HCMV IE1-72 hindered the ability of p53 to bind to its specific DNA sequences, whereas IE2-86 and/or UL84 augmented p53 binding, resulting in an altered DNA-protein complex [226].

Additionally, the induction of the transcription factor NF- $\kappa$ B by HCMV IE proteins has been found to activate cell survival pathways in both normal and tumor cells. Further, HCMV significantly elevates the activity of mitogen-activated protein kinase (MAPK) p38 and ERK1/2 through various mechanisms [227,228]. The expression of HCMV-US28 has been shown to enhance the secretion of biologically active VEGF and activate multiple cellular kinases, thereby promoting glioma growth and invasion [229]. Moreover, it induces the production of IL-6 through NF- $\kappa$ B activation, resulting in the potent activation of the signal transducer and activator of transcription 3 (STAT-3) [230].

### 3.2.2 Evading Tumor Suppressors

By inactivating p53 function and Rb, DNA oncoviruses overpass the G1/S check point and force the cell to enter into the S phase, resulting in unregulated cell division and tumor formation. Numerous studies have documented HCMV interference with the cell cycle, showing p53 and Rb being targeted. HCMV-IE1, and IE2 allow the evasion of tumor suppressors p53 and Rb [215]. HCMV-IE1 and IE2 proteins interact with p53 *in vitro* and *in vivo*, transcriptionally inactivating the latter [226,231]. The aforementioned HCMV-IE proteins have the potential to deactivate the Rb protein family, which consequently stimulates the entry of cells into the S phase of the cell cycle [232]. Additionally, the IE1 protein drives cell cycle progression toward the G1/S transition point by increasing the expression of E2F-responsive genes. Among these genes are cellular regulators of the cell cycle, as well as essential enzymes required for DNA precursor synthesis and the initiation of cellular DNA replication, such as cyclin E and cdk-2 [233]. HCMV pUL97 phosphorylates and renders inactive proteins belonging to the Rb family, facilitating the promotion of the cell cycle. Additionally, the pUL82 protein works to reduce the levels of Rb family proteins. One such protein is encoded by the viral UL82 gene and is termed pp71; HCMV pp71 protein targets the hypo-phosphorylated forms of the Rb proteins for proteasome-dependent degradation through a ubiquitin-independent pathway [234]. In HCMV-infected HMECs, there is a decrease in the detection of the Rb protein and an enhanced expression of the UL82 transcript [235]. Further, a study showed that the proliferation of IE1-expressing glioblastoma cells depends on p53 and Rb inhibition and PI3K/AKT activation [236].

### 3.2.3 Activating Invasion and Metastasis

The capacity for invasion and formation of distant metastases are recognized as critical characteristics of tumor cells, regulated by a complex network of interactions and regulatory mechanisms. This enables them to intravasate into blood and lymphatic vessels while evading immune surveillance, displaying anchorage-independent growth. Subsequently, cancer cells extravasate from these vessels into their target tissues, where they establish micrometastases [219]. The epithelial-mesenchymal transition (EMT) process plays a significant role in this cascade of invasion and metastasis [222]. Studies have shown that persistent HCMV infection of neuroblastoma cells leads to increased motility and adhesion of human endothelial cells [237]. It's worth noting that the transmigration of tumor cells is facilitated by the focal disruption of endothelial cell integrity, mediated by the activation of  $\beta 1\alpha 5$  integrin on the surface of infected tumor cells. This phenomenon is accompanied by HCMV-induced downregulation of neural cell adhesion molecule (NCAM; CD56) receptors, which promotes transendothelial penetration [238]. HCMV infection augments glioma invasiveness by enhancing extracellular matrix-dependent migration and invasion, specifically through the phosphorylation of FAK at Tyrosine397, which is observed exclusively in human malignant glioma cells [239]. In neuroblastoma cell lines persistently infected with HCMV, gene microarray analysis has revealed an upregulation of genes associated with cancer cell invasion [240]. Furthermore, vIL-10 and US28 will enhance cancer cell invasion and metastasis [241].

### 3.2.4 Enabling Replicative Immortality

It is widely acknowledged that cancer cells possess the capability for endless replication. This immortality is achieved by their capacity to overcome two significant barriers to proliferation: senescence and crisis, with the latter eventually resulting in cell death [219]. Additionally, tumor cells find ways to evade the loss of telomeres, which protect the ends of chromosomes, thereby preventing telomere erosion and the entry into crisis, enabling them to sustain unlimited proliferation [222]. HCMV has been demonstrated to trigger the continuous expression of human telomerase reverse transcriptase (hTERT) and the activation of telomerase. In this context, CMV-IE and hTERT proteins were observed to co-localize in human primary glioblastoma multiforme cells, and their levels correlated with each other. This effect is facilitated by IE1's ability to

stimulate telomerase activity and promote telomere lengthening through a specific interaction with the hTERT promoter [242]. Previously, in our laboratory, the infection of HMECs with HCMV-DB resulted in the overexpression of hTERT mRNA and increased telomerase activity [209].

### 3.2.5 Inducing Angiogenesis

During the progression of tumors, an "angiogenic switch" is triggered to ensure the continuous development of new blood vessels that serve not only to sustain tumor growth by providing essential nutrients and oxygen but also facilitate the removal of metabolic waste products and enable the tumor to enter the process of hematogenous metastasis [222]. This process primarily involves the induction of pro-angiogenic factors or the suppression of antiangiogenic signals [219]. HCMV typically promotes angiogenesis through both direct and indirect mechanisms. Infections occurring near blood vessels may stimulate angiogenesis by releasing angiogenic factors or by increasing local inflammation [243]. When fibroblasts and endothelial cells are infected, they promote the synthesis and release of various angiogenic factors that facilitate multiple stages of angiogenesis [244]. US28-induced angiogenic activity, characterized by the production of VEGF, is initiated through an increase in cyclooxygenase-2 (COX-2) expression mediated by US28, which activates the NF- $\kappa$ B pathway [245]. Furthermore, HCMV infection of endothelial cells induces an angiogenic response through viral binding to the epidermal growth factor receptor, as well as  $\beta$ 1 and  $\beta$ 3 integrins, leading to the activation of the phosphatidylinositol 3-kinase (PI3k) and mitogen-activated protein kinase signaling pathways [246]. HCMV also infects lymphatic endothelial cells and induces the release of a set of molecules that promote angiogenesis and lymphangiogenesis. These molecules include IL-6, granulocyte-macrophage colony-stimulating factor, and IL-8 [247,248]. In addition, HCMV induces the production of proinflammatory and angiogenic cytokines in retinal pericytes, contributing to angiogenesis in conditions such as retinopathy and congenital ocular disease [249].

### 3.2.6 Resisting Cell Death

In addition to sustaining continuous proliferation and manipulating cellular growth processes, cancer cells possess the ability to avoid pathways leading to cell death. While three primary pathways apoptosis, necrosis, and autophagy can potentially induce cell death, their activation needs to be regulated by tumor cells. Apoptosis, in particular, has been extensively studied in the

context of malignant transformation, where the initiation of apoptosis is finely tuned by balancing pro-apoptotic and anti-apoptotic factors [220,222]. Numerous HCMV proteins can modulate apoptosis through diverse mechanisms, ultimately resulting in the inhibition of both intrinsic and extrinsic apoptotic signaling pathways [250]. For instance, pUL38, UL37, and US21 have been demonstrated to exert anti-apoptotic effects [70,251,252]. Notably, HCMV encodes a cell death-suppressing protein known as viral mitochondria-localized inhibitor of apoptosis (vMIA), which binds to Bcl2 associated X (BAX) and impedes BAX-mediated mitochondrial membrane permeabilization by sequestering BAX within the mitochondria [253]. Another HCMV protein, pUL36, interacts with pro-caspase-8 thereby inhibiting apoptosis initiated through death receptors [254]. Moreover, HCMV adopts strategies to evade extrinsic pro-apoptotic pathways by downregulating the cell surface expression of death receptors, including tumor necrosis factor receptor 1 (TNFR1), TNF-related apoptosis-inducing ligand (TRAIL) receptor 1, TRAIL receptor 2, and Fas [255]. Additionally, the long non-coding RNA lncRNA2.7 directly interacts with the gene associated with retinoid/interferon-induced mortality-19 (GRIM-19), leading to the stabilization of mitochondrial respiratory chain complex I and the continuous production of ATP [256]. Furthermore, HCMV employs alternative mechanisms to block apoptosis, such as the expression of the anti-apoptotic Bcl-2 protein or the inhibition of p53-mediated apoptosis by HCMV-IE2 [257,258].

While the role of autophagy in cancer regulation is a subject of contention, an increasing body of research predominantly underscores its pro-survival function in promoting cancer progression and metastasis [259]. Autophagy has the capacity to limit viral infections, but persistent viruses have developed diverse strategies to evade or hinder multiple stages of the autophagic process [260]. For instance, HCMV employs mechanisms to counteract autophagy, one of which involves TRS1 in addition to IRS1 that hinder autophagy by binding to Beclin 1 [260,261]. Autophagy also regulates the properties of CSCs by contributing to the maintenance of stemness, induction of recurrence, as well as tumor resistance [262]. On the other hand, in early tumorigenesis, it acts as a tumor suppressor and survival pathway by preventing the accumulation of damaged proteins and organelles [263]. Hence, autophagy plays dual roles in tumor promotion and suppression [262,263].

### 3.2.7 Evading Immune Suppression

HCMV has developed various immune evasion tactics to manipulate the host immune system, enhancing its infection and spread within the host (**Figure 8**) [70]. A significant strategy involves hindering MHC class I-restricted antigen presentation. During the immediate early phase of HCMV infection, cytotoxic T-lymphocytes (CTLs) counteract antigenic peptides produced by the IE1 transcription factor. However, the matrix protein pp65, which possesses kinase activity, phosphorylates IE1, specifically blocking the presentation of IE-derived antigenic peptides. This allows HCMV to evade immune recognition of early viral proteins. Additionally, pp65 is introduced directly into cells during viral fusion, enabling HCMV to escape immunological surveillance until other immune evasion-related proteins are released. HCMV-specific viral proteins and genes associated with host interferon responses further inhibit NK cell detection and activation, as well as hinder the recognition of CD4<sup>+</sup> and CD8<sup>+</sup> T-cells by preventing MHC Class I and II antigen processing and presentation. Furthermore, HCMV-infected cells produce a viral IL-10 homolog, which suppresses CD4<sup>+</sup> and CD8<sup>+</sup> T-cell responses [70].

function as energy source to support distant dissemination of cells. Notably, not only LD density but also their motility was correlated with cancer aggressiveness [264]. Further, HCMV infection disrupts cellular energy metabolism and induces significant alterations in metabolic processes including increased glucose uptake, elevated glycolysis, diversion of glucose carbon, and the induction of the Warburg effect [46]. HCMV-IE1 protein appears to modulate the mRNA levels, eliminating glucose transporter 1 (GLUT1) mRNA and increasing GLUT4 mRNA. The elevated GLUT4 in infected cells is driven onto the cell surface, verifying that glucose uptake increases regardless of Akt function [265]. Further, HCMV-pUL38 is capable of initiating glycolytic activation and prompting the breakdown of specific amino acids [266]; HCMV-pUL13 targets mitochondrial cristae architecture to increase cellular respiration during infection [267].

### 3.2.9 Enabling Characteristics: Genomic Instability, Mutation, and Tumor-promoting Inflammation

Throughout the multistep progression of tumors, cancer cells often exhibit an increased rate of mutations, wherein a favorable mutant genotype provides a selective advantage to certain subclones of cells. This advantage supports their proliferation and eventual dominance within a local tissue environment [219,220]. Several mechanisms contribute to this phenomenon, including increased sensitivity to mutagenic agents, compromised surveillance systems responsible for monitoring genomic integrity (such as p53), as well as increased defects in detecting DNA damage and activating the repair mechanisms responsible for DNA damage repair and deactivating mutagenic substances. On the other hand, the inflammatory response associated with tumor growth has been linked to enhanced tumorigenesis and progression. This is attributed to the release of various chemicals, notably mutagenic reactive oxygen species, as well as factors promoting growth, survival, and angiogenesis. These factors collectively facilitate proliferative signaling, inhibit cell death, and enable processes like angiogenesis, invasion, and metastasis [219].

In the context of HCMV infection, it has been shown that HCMV-UL76 induces DNA damage as well as the accumulation of chromosome abnormalities, including micronuclei, misaligned chromosomes, and issues like lagging and bridging [268]. Further, viral replication activates the checkpoint response to DNA double-strand breaks, and this replication alters the localization of

checkpoint proteins to the cytoplasm, thus inhibiting the signaling pathway [269]. Furthermore, lytic HCMV infection disrupts ataxia telangiectasia mutated protein (ATM)-related kinases and triggers DNA damage responses [270]. Specifically, IE1 has been shown to activate ATM kinase [223], while E2F1 contributes to the accumulation of the gamma histone variant H2AX ( $\gamma$ H2AX) during HCMV infection or IE protein expression [271]. On the other hand, pUS28 exacerbates tumor-related inflammation by inducing the production of various proinflammatory mediators, including IL-6, regulated on activation normal T expressed and secreted (RANTES), monocyte chemoattractant protein-1 (MCP-1), and fractalkine [272,273]. HCMV augments the recruitment of leukocytes and prompts the production of proinflammatory substances like IL-8 and IL-6, along with the expression of the leukocyte intercellular adhesion molecule 1 (ICAM-1) receptor [274–276]. Furthermore, CMV infection generates intracellular reactive oxygen intermediates in smooth muscle cells and human diploid fibroblasts [277,278].

### 3.2.10 Tumor Promoting Microenvironment

As cancer evolves, it can resist immune clearance by prompting tolerance in the presence of tumor-associated inflammatory cells. Consequently, a tumor microenvironment (TME) is generated and controlled by tumor-induced molecular and cellular interactions in which immune cells not only fail to exert anti-tumor effector functions, but also promote tumor development [279]. HCMV expresses several gene products that modulate the host immune response and promote modifications in non-coding RNA and regulatory proteins. These changes are linked to several complications, such as immunosenescence and malignant phenotypes leading to immunosuppressive TME and oncomodulation (**Figure 9**) [70]. NF- $\kappa$ B and PI3K activity play a role in facilitating the HCMV-induced transformation of monocytes into macrophages with a dual phenotype, exhibiting characteristics of both inflammatory macrophages (M1) and immunosuppressive macrophages (M2). In this context, M1 macrophages are responsible for releasing inflammatory factors such as TNF- $\alpha$ , IL-6, and nitric oxide synthase 2, while M2 macrophages exhibit an immunosuppressive profile similar to tumor-associated macrophages (TAMs), characterized by the secretion of immunosuppressive cytokines like TGF- $\beta$  and IL-10 [280]. It's worth noting that a significant portion of TAMs in breast cancer cells display activated M2 features, accompanied by the secretion of elevated levels of immunosuppressive cytokines,

including IL-10, TGF- $\beta$ , and, to a lesser extent, pro-inflammatory cytokines [281]. Notably, research from our laboratory has demonstrated that the highly macrophage-tropic HCMV-DB strain can induce the activation of an M2-like state [282]. This underscores the potential contribution of HCMV infection to the development of neoplastic transformation in breast epithelial cells, partially through the recruitment and polarization of macrophages [283]. The oncomodulatory potential of HCMV catalyzes an oncogenic process by producing viral proteins, helping tumor cells to evade the immune system, and preventing and/or delaying cell death. The lack of HCMV specific cellular immune responses in these immune-privileged tumor sites would definitely enhance HCMV replication. On the other hand, cancer cells on their own can escape immune responses by diverse mechanisms. Thus, the combination of intrinsic cellular with viral immune escape machineries in cancer cells may offer an environment which enhances HCMV replication and boost cancer cells to evade from immune surveillance showing the bidirectional relationship between tumor cells and HCMV [70].

**Figure 9: HCMV Oncomodulation and Its Significance in Tumor Microenvironment.**

Major signaling pathways stimulated by HCMV that modulate the immune landscape. HCMV-infected cells produce elevated levels of interleukin-6 (IL-6) that activates signal transduction *via* IL-6 receptor (IL6R)-STAT3 axis. US28, an active chemokine receptor, also plays a major role in activating STAT3 in cancer cells. The combination of STAT3

activation and the impact of HCMV on cancer cell apoptosis, invasion, migration, adhesion, angiogenesis, and immunogenicity significantly exacerbates malignancy. In contrast to p53 and Rb, the upregulation of Akt, Myc, PD-L1, and CCL2 strongly exerts immunosuppressive and oncomodulatory effects. HCMV-induced alterations in the TME may contribute to oncomodulation [70].

### 3.3 HCMV and Its Association with Breast Cancer

Globally, breast cancer poses a formidable health challenge as it is the most prevalent malignancy accounting for a high number of cancer deaths in women [284]. Breast cancer consists of a group of heterogeneous diseases driven by a multifactorial etiology involving genetic predisposition, hormones, and environmental factors; viruses are considered indisputable causal factors for nearly 20% of all human malignancies [285]. Triple-negative breast cancer (TNBC) comprises 15% of breast cancers globally [286]. Despite its susceptibility to standard chemotherapy, TNBC is highly invasive, has a high relapse tendency, and is associated with a poor overall prognosis [287]. Recently, more significant advances include characterizing the molecular features of TNBC which will maximize the efficacy of certain chemotherapeutic agents and aid in actively exploring novel therapeutic targets [288]. The majority of breast cancers originate from cells lining the milk-forming ducts within the mammary gland, known as carcinomas [289]. Following childbirth, HCMV can be detected in breast milk, potentially spreading to nearby mammary epithelial cells [290]. Moreover, HCMV has the ability to infect macrophages and induce an atypical M1/M2

phenotype that closely resembles the phenotype of tumor-associated macrophages. This alteration is linked to the release of cytokines that play a role in the initiation or promotion of cancer, particularly in cases of breast cancer with a poor prognosis [290]. Furthermore, HCMV antigens and DNA have been identified in tissue biopsies of individuals with breast cancer [291], and there have been reports of elevated serum HCMV IgG antibody levels occurring before the onset of breast cancer in certain women [292]. Further, previous studies demonstrated the ability of HCMV-DB and HCMV-BL strains in transforming primary HMECs into CMV-Transformed HMECs (CTH) cells in vitro [125,209]. CTH cells, which are slow self-renewing cells, undergo diverse stages of the giant cell cycle. They were shown to be heterogeneous, generate PGCCs, exhibit dedifferentiation, and display stemness and EMT/MET features [125,126]. HCMV oncomodulation, molecular mechanisms, and ability to support PGCCs generation might underscore its contribution to oncogenesis, especially breast cancers. The heterogeneity of strains can be linked to distinct properties influencing the virus-transforming potential, cancer types induced, and patient's clinical outcomes.

#### 3.4 The Potential Link Between HCMV and Glioblastoma

GBM, a subtype of adult diffuse glioma, is a primary central nervous system (CNS) tumor presumed to arise from neuroglial stem cells or their progenitors in the subventricular zone [293,294]. There has been a recent paradigm shift, with increasing reliance on molecular information for diagnostic classification and prognostication within gliomas, as seen in the most recent World Health Organization (WHO) classification of CNS tumors [294]. Despite the molecular evolution of GBM, it continues to be an incurable disease with poor survival. HCMV infects neural stem/progenitor cells, and human astrocyte [295–298]. Although HCMV DNA and antigens, especially IE1, have been detected in GBM tissue [236,299], there is no conclusive evidence about HCMV oncogenicity in GBM, and the mechanisms by which the virus might contribute/induce oncogenesis remain elusive. The expression of HCMV proteins and oligonucleotides in high percentage of low- and high-grade malignant gliomas was first reported by Cobbs et al. in 2002 [213]. Although these data do not establish a causal role for HCMV in glioma pathogenesis, existing data indicates that HCMV could facilitate glioma progression. A study showed that HCMV-IE1 protein was detected in 100% of glioblastomas and 82% of low-

grade gliomas upon using immunohistochemistry. They further reported the detection of HCMV-specific oligonucleotides in the same areas of IE1 expression within the tumor. Their finding, as initially described by Cobbs et al. in 2002, is that HCMV IE1 and virus-specific oligonucleotides weren't detected in necrotic areas or outside the tumor margin [236]. Numerous reports have provided evidence of HCMV's presence in GBM, although typically confined to a small subset of cells [300]. Studies have also indicated that viral proteins can dysregulate cellular processes and intensify the malignancy of tumors [70,215,236,300]. Additionally, it has been observed that HCMV IgG seropositivity is linked to reduced overall survival rates among GBM patients [301]. These discoveries hold substantial implications for GBM screening and treatment, as anti-HCMV IgG testing may offer valuable prognostic insights. A study revealed a significant association between HCMV seropositivity and diminished overall survival in GBM patients, especially among those with unmethylated MGMT. This observation suggests that prior HCMV infection may have a noteworthy impact on the outcomes of GBM patients [301]. Consequently, anti-HCMV antibodies may prove to be a valuable prognostic tool in the management of GBM patients. Moreover, GBM cells exhibit HCMV proteins, presenting a unique opportunity for targeted therapy. A study utilized the universal intracellular targeted expression (UNITE) platform to develop a multi-antigen DNA vaccine encoding HCMV proteins pp65, gB, and IE1. The UNITE platform incorporates lysosomal targeting technology, involving the fusion of lysosome-associated membrane protein 1 (LAMP1) with target antigens. This study demonstrates compelling evidence of enhanced antigen presentation through both MHC-I and -II, resulting in a robust antigen-specific CD4 and CD8 T-cell response, along with a potent humoral response [302]. Thus, this research underscores that vaccination with HCMV antigens elicits robust cellular and humoral immune responses, triggering significant anti-tumor activity and leading to improved survival in a mouse model of GBM. Lastly and most recently, it's worth mentioning that Moderna's RNA vaccine for HCMV infection (CMVictory mRNA-1647) is currently undergoing Phase 3 clinical trials (NCT05085366) [303].

### 3.5 The Interplay Between HCMV and Ovarian cancer

Epithelial ovarian cancer (OC), the most common and life-threatening cancer amongst gynecologic malignancies, has a 5-year age-standardized survival rate of 30–40%. Nearly 75% of

all OC cases are diagnosed at late stages [304]. Despite the advances in treatment modalities, the overall survival remains low for stage III and stage IV accounting for 40% and 20%, respectively [305,306]. Currently, infection-triggered chronic inflammation is recognized as a crucial mechanism in the progression and spread of OC. In alignment with this observation, recent studies have identified elevated expressions of HCMV proteins in OC tissue samples that have been associated with poor survival outcomes [307]. One study revealed that HCMV-IE protein expression was present in 82% of OC cases and 36% of benign tumors, while pp65 was detected in 97% of EOC cases and 63% of benign tumors. Notably, pronounced HCMV-IE expression was correlated with a shorter median overall survival [308]. Additionally, the presence of HCMV DNA was found in 70% of cancerous ovarian tissues, significantly exceeding the detection rate in benign tumor cases [307]. These findings suggest that HCMV infection might potentially facilitate the progression of cancer. Within the ovarian cancer TME, active HCMV infection may directly contribute to OC progression. Once HCMV infects host cells, it initiates mechanisms to counteract key antiviral immune responses necessary for infection control. These mechanisms involve the secretion of immunosuppressive cytokines and the impairment of cell-mediated immune responses, which are also crucial for restraining tumor growth [304]. Previously existing data showed the detection of HCMV-gB by PCR in approximately 50% of OC tissues, with 80% of these cases being late-stage invasive tumors, suggesting that HCMV infection within the TME could potentially promote cancer progression or metastasis [304]. Another recent study by Radestad et al. explored the prevalence of HCMV in ovarian cancer and its association with clinical outcomes. Their research indicated higher levels of HCMV-IgG, HCMV-IE proteins, and pp65 proteins in OC patients with malignant or benign ovarian epithelial tumors compared to control subjects [309]. This observation underscores the need to investigate whether administering anti-HCMV treatment to OC patients experiencing active HCMV reactivation in their TME should be considered in future therapeutic approaches. In conclusion, HCMV proteins and nucleic acids are frequently detected at varying levels in high-grade serous ovarian carcinoma. The shorter median overall survival of patients with HCMV-IE and pp65 in their tumors underscores the imperative to further explore the role of HCMV in ovarian cancer patients.

## Chapter 4

### 4. Emerging Threats: Decoding The Molecular Pathways in Cancer Development and Understanding Viral Variants

#### 4.1 Decoding The Molecular Pathways in Cancer Development

The cumulative body of evidence underscores the pivotal roles played by EZH2 and Myc in the initiation of cancer and maintenance of stem cell properties [310]. Being the enzymatic subunit of polycomb repressive complex 2 (PRC2), EZH2 is a histone-lysine N-methyltransferase responsible of transcriptional silencing [311]. EZH2 dysregulation was associated with the development, progression, and therapeutic resistance of many tumors [312,313]. Additionally, it was shown to expand the stem cell pool and the tumor-initiating cells in glioma, breast, ovarian, and prostate cancer, hence enhancing accelerated initiation, metastasis, invasion and growth [314–316]. In breast cancer pathogenesis, EZH2 overexpression assumes a critical role as it suppresses the expression of early growth response 1 (EGR1), thus inhibiting EGR1-mediated tumor-suppressive signals [317]. Moreover, EZH2 mediates the stability of ribosomal DNA by silencing PHACTR2-AS1, thereby fostering genomic instability and promoting growth and metastasis in breast cancer [318]. Further, EZH2 was demonstrated to be overexpressed in GBM tissues harboring HCMV [319]. EZH2 was also shown to be recruited to the major immediate early promoter (MIEP) in CD14+ monocytes where HCMV establishes latent infection in vivo [320]. Furthermore, several studies showed that EZH2 overexpression is associated with HGSOC [321,322]. A study reported that EZH2 degradation profoundly blocked ovarian tumor cell proliferation and tumorigenesis in vitro and in vivo [323]. Another study revealed that invading PGCCs possess strong EZH2 expression [324]. Since EZH2 enhances cell proliferation, inhibits apoptosis, promotes angiogenesis, metastasis and therapy resistance in several tumors, inhibiting EZH2 suggests an effectual therapeutic strategy [325,326].

EZH2 was identified as a downstream target of Myc oncogene, the latter coordinately regulating EZH2 through transcriptional and post-transcriptional mechanisms during tumor initiation and disease progression [327]. Myc has been shown to stimulate EZH2 expression through direct binding and activation of its promoter, as well as by suppressing its negative regulator, miR-26a, or by directly repressing miR-137 [327,328]. The Myc-miR-137-EZH2 pathway has been linked

to cisplatin resistance in ovarian cancer [329]. Additionally, bromodomain-4 protein (BRD4) was shown to positively regulate EZH2 transcription through Myc upregulation [330]. Interestingly, Myc activation has been widely reported in the progression of breast cancer, especially in triple-negative breast cancer and in tumors that exhibit drug resistance, much like aggressive medulloblastoma tumors where elevated Myc levels are associated with increased EZH2 expression [126,331]. By uncoupling DNA replication from mitosis, Myc overexpression can induce DNA replication, thus opening the door toward polyploidy [332]. This intricate relationship between Myc, polyploidy, and cancer has been previously demonstrated [333], with Myc correlating with nuclear pleomorphism in both primary and metastatic renal cell carcinomas. Moreover, Myc has been found overexpressed in GBM; its expression correlates with glioma grade where 60-80% of GBM reveal elevated Myc levels [334]. In glioma cells, EZH2 knockdown depleted Myc expression [335]. Further, Myc direct transcriptional regulation by EZH2 may establish a new mechanism underlying glioma cancer stem cell maintenance [336]. Similarly, enhanced Myc expression have been observed in 20-50% of ovarian carcinoma [337,338].

#### 4.2 Viral Variants and Their Oncogenic Potential

Viral variants acquire diverse capacities to manipulate host cell machinery, making them more or less efficient at promoting cellular transformation and cancer development. Some variants may be more efficient at evading the immune response, more prone to causing persistent infections, or more effective at disrupting cellular processes that regulate cell growth and division [339–341]. Oncoviruses could serve to emphasize the significance of HCMV in processes related to cellular transformation and oncogenesis. To start with, HPV strains were classified into high- and low-risk strains after being isolated from different lesions. These discoveries were shown to radically alter the tumor diagnosis, prognosis, and prevention approaches [342,343]. Low-risk HPV strains were generally not strongly linked to cancer development, for instance HPV-6 and HPV-11. On the other hand, certain high-risk HPV strains were strongly associated with the development of various cancers through persistent infections that may cause various cellular changes. The most notable high-risk HPV strains include HPV-16 and HPV-18, HPV-31, HPV-33, and HPV-45 [344,345]. Researchers have identified specific genetic sequences within high-risk HPV types that are associated with increased cellular transformation. The HPV E7 carboxyl terminus contains two

copies of a CXXC motif that are separated by a 29-amino-acid spacer. This domain may function as a dimerization domain [346]. Like adenovirus E1A and SV40 T antigen, the HPV E7 proteins interact with pRB and the related “pocket proteins” p107 and p130 through a conserved LXCXE sequence within the conserved region 2 sequences thereby impairing their ability to control cell-cycle dependent transcription [346,347]. These sequences often involve the viral E6 and E7 genes, which produce proteins that interfere with cellular regulatory mechanisms and contribute to the transformation of normal cells into cancerous cells. Variations in these genes can affect the severity of their oncogenic effects. Additionally, KSHV isolates were identified in patients of different geographical regions, indicating the importance of these newly isolated strains in developing better diagnostic procedures and novel treatment approaches in the context of KSHV-associated malignancies as well as enriching potential vaccine studies [348–350]. The cytoplasmic tail of KSHV-K1 protein contains two SH2 binding motifs that together constitute an immunoreceptor tyrosine-based activation motif (ITAM) [351]. ITAM motif consisting of six conserved amino acid residues spaced precisely over 26-amino acid sequence, (D/E)X<sub>7</sub>(D/E)X<sub>2</sub>YX<sub>2</sub>LX<sub>7</sub>YX<sub>2</sub>L/I [352], is able to constitutively induce angiogenic and inflammatory responses via AKT and NFκB [353]. Further, EBV was initially categorized into two primary sub-types, namely type 1 and type 2, based on the genetic sequences of two EBV-encoded genes, EBNA2 and EBNA3. Type 1 is widespread globally, whereas type 2 is primarily found in sub-Saharan Africa. Currently, more than 71 distinct EBV strains have been documented. These EBV variants exhibit varying replication characteristics, and individuals can potentially be infected with multiple strains. It has been observed that certain EBV strains possess a higher oncogenic potential compared to others. For instance, the EBV strain M81, derived from nasopharyngeal carcinoma (NPC), exhibits an elevated rate of replication in B cells and a remarkably strong tendency to infect epithelial cells [354,355]. Ongoing research efforts are increasingly delving into the diversity of EBV latent and lytic genes among the various EBV strains, aiming to discover high-risk EBV strains. This attempt holds the potential to identify individuals at a higher risk of infection and pave the way for the development of effective EBV vaccines and anti-EBV T-cell therapies [354].

Nonetheless, it is noteworthy that the oncogenic potency of HCMV clinical strains varies between low and high-risk strains. HCMV-DB and HCMV-BL have been classified as high-risk strains in

which they possessed their oncogenic potentials in acutely infected HMECs in vitro showing sustained transformation [125,126,209,356]. Upon infection with HCMV high-risk strains, there was an increase in the activation of Myc and EZH2 as well as the induction of polyploidy. This activation of the mentioned axis was significantly more pronounced in CTH cells. Moreover, it has been previously shown that the high-risk HCMV-BL strain robustly induces Myc expression while suppressing p53 levels [126]. This can enhance the replicative potential of stem cells and the reprogramming of progenitor cells in breast cancer, as Myc is identified as a transcriptional target of p53 in mammary stem cells and is activated upon p53 loss. Furthermore, HCMV-DB increases pRb repression [125], with the pRB-E2F pathway known to regulate the expression of EZH2 [357]. Previously, in experiments involving the infection of HMECs with KM, FS, and TB40/E strains, no significant activation of molecular oncogenic pathways was observed upon acute infection, nor were CTH cells detected in cultures [126,356]. This was especially notable when compared to the high-risk HCMV-DB and BL strains. Consequently, it is reasonable to classify HCMV-KM, FS, and TB40/E strains as low-risk strains. This conclusion is consistent with the absence of colony formation in soft agar assays following seeding HMECs infected with HCMV-KM, FS, and TB40/E strains. This underscores the hypothesis that the HCMV high-risk strains, namely DB and BL differentially induce Myc upregulation and consequently stimulating EZH2 overexpression and polyploidy induction, thus pointing to the presence of the Myc/EZH2/PGCCs axis as a key factor underlying these observed results [126]. With regard to immune responses, Myc suppresses immune surveillance by modulating the expression of the innate immune regulator (CD47, also known as integrin-associated protein) and the adaptive immune checkpoint namely, programmed death ligand 1 (PD-L1, also known as CD274 and B7-H1) [358]. Further, Myc suppresses thrombospondin-1 gene [359], type 1 IFN [360], interleukin-2, and perforin [358]. Hence, Myc initiates and maintains tumorigenesis through the modulation of immune regulatory molecules [361]. These high-risk strains were also characterized by PI3K/Akt pathway activation. PI3K/Akt activation induced inflammation and immunosuppression through nitric oxide synthase (NOS) overexpression; thus, resulting in tumor initiation *via* the activated Notch pathway leading to tumor progression. On the other hand, suppression or mutation of p53 has been shown to decrease MHC-I presentation, increase STAT3 phosphorylation,

upregulate PD-L1 *via* microRNA (miR34), elevate pro-inflammatory chemokine and cytokine production, and indirectly upregulate the expression of chemokine receptors (CXCR4 and CXCR5). Loss of Rb leads to the increase in CCL2 and IL6 secretion and this is because of the elevated fatty acid oxidation (FAO) activity and enhanced mitochondrial superoxide (MS) production. Indeed, those molecular alterations have been linked to immune suppression in the TME [70].

## Chapter 5

### 5. Study Objectives

#### **Objective 1:**

In the context of breast cancer, previous studies that were conducted by our research team demonstrated the ability of HCMV-DB and HCMV-BL strains in transforming primary HMECs into CMV-Transformed HMECs (CTH) cells in vitro. CTH cells, which are slow self-renewing cells, undergo diverse stages of the giant cell cycle. They were shown to be heterogeneous, generate PGCCs, exhibit dedifferentiation, and display stemness and EMT/MET features. Herein, we aimed to:

- Characterize two HCMV strains, B544 and B693, isolated from TNBC biopsies and assess their transformation potential in vitro.
- Evaluate the resulting cellular phenotype and examine the genetic and molecular features induced by these strains.
- Examine the sensitivity of CTH cells to combination therapy using paclitaxel (PTX) and ganciclovir (GCV).

#### **Objective 2:**

With regards to GBM, since HCMV-DB and BL clinical strains previously transformed HMECs into CTH cells and as HCMV has been detected in malignant gliomas, we aimed to discover its transforming potential in human astrocytes (HAs) by setting the following objectives:

- Screening HCMV-DB and BL clinical strains for their transforming capacity in HAs and investigating the molecular and cellular characteristics of CMV-induced glioblastoma cells (CEGBCs) that emerge during long-term cultures.
- Examining the impact of temozolomide (TMZ), Ganciclovir (GCV), and the EZH2 inhibitor (GSK 343) on this glioblastoma model.

- Exploring the potential link between the triad of HCMV, CEGBCs and EZH2, as well as the potential interrelation with Myc in the context of glioblastoma carcinogenesis.
- Investigating the morphological and phenotypic characteristics of CEGBCs and assess the potential implication of Myc and EZH2 in both CEGBCs and GBM biopsies.
- Isolating eleven clinical HCMV strains from GBM biopsies, analyzing their oncogenic, stemness, and invasiveness properties when cultured on HAs, as well as evaluating the potential effectiveness of combination therapy in curtailing these effects.

### **Objective 3:**

In the context of ovarian cancer and since HCMV-DB and BL clinical strains previously transformed HMECs and HAs into CTH and CEGBCs cells, respectively, we decided to investigate the potential association between HCMV infection and epithelial ovarian cancer, particularly in the case of high-grade serous ovarian cancer (HGSOC) through setting the objectives below:

- Assessing the transforming capacities of the two high-risk clinical strains namely, HCMV-DB and HCMV-BL, as well as exploring the molecular and cellular characteristics that emerged during long-term cultures of "CMV-transformed Ovarian cells" (CTO cells).
- Isolating clinical HCMV strains from HGSOC biopsies displaying high EZH2 expression and investigating their oncogenic and stemness properties when cultured on OECs.
- Evaluating the efficacy of EZH2 inhibitors in curtailing CTO's oncogenic and stemness features.

## Chapter 6

### 6. Materials And Methods

#### 6.1 Reagents

All the reagents that were used including primers, antibodies, and therapies were provided in the tables below (Table 4, Table 5, and Table 6).

## 6.2 Cell Cultures

Human primary mammary epithelial cells (HMECs, A10565) were purchased from Life Technologies (Carlsbad, CA, USA), and were cultured in HMEC medium (Life Technologies) supplemented with HMEC supplement and bovine pituitary extract (Life Technologies). Human breast cancer cell lines MDA-MB231 and MCF7 were obtained from Institut Hiscia (Arlesheim, Switzerland). Human embryonic lung fibroblasts (MRC5, 84002) were purchased from RD-Biotech (Besançon, France). MRC5, MDA-MB231 and MCF7 cells were grown in Dulbecco's modified Eagle medium (DMEM) (PAN-Biotech, Aidenbach, Germany) supplemented with 10% fetal bovine serum (Dutscher, Bernolsheim, France) and penicillin (100U/mL)-streptomycin (100 $\mu$ g/mL) (Life Technologies, Eugene, OR). Primary human astrocytes (HAs) were purchased from Innoprot (Derio, Spain) and cultivated in astrocytes medium (Innoprot). Human ovarian

surface epithelial cells (HOSE cells or OECs, as mentioned in our study) were purchased from Innoprot (Derio, Spain), and cultivated in ovarian epithelial cell medium (serum-free) supplemented with ovarian epithelial cell growth supplement (OEpiCGS) and penicillin/streptomycin solution (P60132, Innoprot). To note that, HOSE cells or OECs were isolated from healthy human ovaries, as mentioned in the technical data sheet (P10982, Innoprot).

CTH and CTO cells emerging following chronic HCMV infection were cultured in the same condition as HMECs and OECs, respectively. With regards to CEGBCs isolation and growth, upon the appearance of large cellular clusters/structures in HAs cultures that were infected with HCMV-DB and BL isolates, clusters were gently detached. CEGBCs were initially cultivated in HAs medium complemented with low levels of fetal bovine serum (2%) as per the manufacturer's recommendations. At day 150 post-infection, since CEGBCs resemble stem cells compared to uninfected HAs, serum was excluded and this is to fit with the optimal conditions of serum-free stemness growth as requested for glioblastoma cell cultures [362]. Serum was omitted at day 5 post-infection of HAs with the HCMV strains that were isolated from GBM biopsies. CTH, CEGBCs, and CTO cultures used in this study were maintained for at least 9 months in culture.

All cells were cultured under standard conditions (37°C, 5% CO<sub>2</sub>, 95% humidity). Cultures were verified as mycoplasma-free as determined by monthly screenings (VenorGem classic mycoplasma detection, Minerva Biolabs).

### 6.3 HCMV Isolates Growth and Detection

Clinical HCMV strains, namely HCMV-DB (GenBank KT959235), BL (GenBank MW980585), KM, and FS were isolated from patients that were hospitalized at Besançon University Hospital (France) as described previously [125,209]. Data corresponding to TNBC biopsies and other HCMV strains were reported previously [125,126]. Cell-free virus stocks and infections were performed as previously detailed [125]; to prepare these stocks, HCMV strains were propagated in MRC5 cells for only few passages to avoid losing the ULb' region. It is worth mentioning that careful screening of our viral stocks was conducted to rule out the presence of other oncoviruses. Infections of cells (HMECs, HAs, MRC5, and OECs), quantification of viral replication, and HCMV detection were performed as previously described [125,126]. Briefly, the aforementioned

cells ( $1 \times 10^6$ ) infection with the clinical isolates was performed at a multiplicity of infection (MOI) of 1. Cells were incubated at 37 °C for two hours, after which the inoculum was discarded, and the cell monolayer was washed three times using 1X PBS and afterwards covered with fresh medium. HAs ( $3 \times 10^6$ ) cells infection with HSV was performed at a MOI of 1.

For HCMV quantification, cell-free infectious supernatant was collected, DNA was isolated (EZNA Blood DNA Kit, D3392-02, Omega BIO-TEK, Norcross, GA) and real-time quantitative PCR (qPCR) was performed using a Stratagene Mx3005P thermocycler (Agilent Technologies, Santa Clara, CA) and IE1 primers. Where specified, UL69 as well as HCMV lncRNA4.9 were detected by the qPCR assay. qPCR was performed using a KAPA SYBR FAST Master Mix (KAPA BIOSYSTEMS, KK4601, Potters Bar, UK); reactions were activated at 95 °C for 10 min, followed by 50 cycles (15 seconds at 95 °C and 1 min at 60 °C). Results were collected and analyzed using MxPro qPCR software.

#### 6.4 Microscopy

Olympus optical microscope (Olympus Corporation, Tokyo, Japan) and OPTIKA digital camera (Optica Microscopy, Ponteranica, Italy) were used to monitor the short and long-term cultures of infected HMECs, MRC5, HAs, and OECs including CTH, CEGBCs, and CTO cells.

Confocal microscopy imaging for all the aforementioned cells was performed as described previously [125]. Briefly, cells were washed with 1X PBS, fixed and permeabilized (BD Cytotfix/Cytoperm, 554722) and stained with primary antibodies and their corresponding secondary antibodies listed in **Table 5**. For visualization of the nucleus and the cytoplasm, DAPI (4', 6'-diamidino-2- phenylindole) and phalloidin staining respectively were performed according to the manufacturer's protocol. Post-staining, the slides were assessed using a 63× oil immersion objective lens with a Carl-Zeiss confocal microscope (Jena, Germany); images were analyzed using ZenBlue Software (Carl-Zeiss Microscopy GmbH).

#### 6.5 Soft Agar Colony Formation Assay

Colony formation in soft agar seeded with uninfected HMECs, B544, B693, DB, and BL-infected HMECs, untreated and PTX/GCV-treated CTH cells, uninfected HAs, CEGBCs, uninfected

OECs, and CTO cells was carried out as mentioned previously [125]. MCF7 and MDA-MB231 were used as positive controls. Briefly, cells were assayed using Cell Biolabs Cytosolic Cell Transformation Assay kit (Colorimetric assay, CB135; Cell Biolabs Inc., San Diego, CA) as per the manufacturer's protocol. The provided MTT solution and a microplate reader (A570 nm) were used for detection and quantification of the formation of colonies in soft agar (Cayman Chemical, Ann Arbor, MI). Olympus optical microscope (Olympus Corporation, Tokyo, Japan) and OPTIKA digital camera (Optica Microscopy, Ponteranica, Italy) were used to observe the formed colonies.

#### 6.6 Tumorsphere and Spheroid formation Assays

Tumorsphere formation by uninfected HMECs and HMECs infected with HCMV-B544 and HCMV-B693 was assayed using StemXVivo serum-free tumorsphere media (R&D Systems) supplemented with heparin (2 U/ml) (Sigma) and hydrocortisone (0.5 microg/ml) (Sigma) following the manufacturer's protocol and as described previously [125].

Spheroids of CEGBCs were prepared as described previously [363,364]. Single cells ( $1 \times 10^4$ ) isolated by accutase were seeded in a serum-free astrocytes medium containing methylcellulose. Where indicated, drugs were mixed in serum-free astrocytes medium with 0.4% methylcellulose. Treatment was renewed daily. Spheroid size and surface area were determined using the ImageJ software, taking the mean length of the major and minor axis of the spheroid at a given time point compared to the initial measurements at time zero. Spheroids of OECs were prepared as described previously [365]. Single cells ( $1 \times 10^4$ ) isolated by accutase were seeded in a serum-free OECs medium containing methylcellulose.

#### 6.7 Flow Cytometry Analysis

Cells ( $1 \times 10^5$ ) were collected from uninfected HMECs, HAs, OECs, as well as CTH cells, HCMV-infected HAs, CEGBCs, HCMV-infected OECs, and CTO cells including treated cells (where indicated). Cells were fixed, permeabilized, and stained as previously reported [125,126]. Briefly, cells were fixed and permeabilized using 100  $\mu$ l of BD Biosciences Cytotfix/Cytoperm solution for 20 minutes at 4°C and washed with BD Biosciences 1X BD perm/wash solution. One half of the cells were stained using the respective primary antibody and the remaining cells were mock stained

to identify secondary antibody background staining. Cells were incubated at 4°C for 1 hour in the dark, washed twice with BD Biosciences 1X BD perm/wash solution and incubated at 4°C for 1 hour in the dark with the corresponding secondary antibody. Cells were then washed twice and subjected to cytofluorometric analysis. For cell cycle analysis, uninfected OECs or CTO cells were washed in 1X PBS, fixed in 70% ethanol, and resuspended in 50 µg/ml propidium iodide (P3566, life technologies, Eugene, USA) with 0.1 mg/ml RNase (R4642, Sigma-Aldrich, Saint-Louis, MO, USA), then incubated at 37°C for 30 min as described previously. Cytofluorometric analysis was achieved using a BD LSRFortessa X-20 (BD Biosciences) flow cytometer. FACSDiva software (BD Biosciences) was used for data collection and analysis.

### 6.8 Western Blotting

Expression of IE1, pp65, Myc, EZH2, Akt, and pAkt in uninfected HAs and HCMV-infected HAs as well as IE1, pp65, Myc, EZH2, Sox2, Nanog, E-cadherin, and vimentin expression in uninfected OECs, HCMV-infected OECs and CTO cells were assessed as described previously [125]. Densitometry using ImageJ 1.40 software (National Institutes of Health, Bethesda, MA, USA) was applied to quantify protein levels.  $\beta$ -actin was used as a loading control.

### 6.9 RT<sup>2</sup> Profiler PCR Array

The RT<sup>2</sup> profiler PCR array was performed as detailed previously [356]. Total RNA was extracted from uninfected HAs, and CEGBCs-DB and BL using an RNA extraction kit (EZNA Total kit I, Omega BIO-TEK). Afterwards, cDNA was synthesized using the SuperScript IV First-Strand Synthesis kit (Invitrogen, Carlsbad, CA, USA) following the manufacturer's protocol. RT<sup>2</sup> Profiler PCR Arrays for human oncogenes & tumor suppressor genes (PAHS502ZR) (from Qiagen, Germantown, MD, USA) were performed using Mx3005P real-time PCR system as per manufacturer's instructions. Fold regulation was analyzed using the delta-delta Ct method [356,366].

### 6.10 RNA Cross-linking Immunoprecipitation (RNA CLIP) assay

RNA CLIP assay was performed on CEGBCs and uninfected HAs as previously reported [126,320]. qPCR analysis of EZH2 immunoprecipitated samples (IP EZH2) and negative control

(IP IgG) were normalized with respect to each input and expressed as  $(2^{-\Delta Ct}) \times 100$  (% Input) as previously reported [126].

#### 6.11 Assessment of telomerase activity

Uninfected OECs and CTO cells were collected, washed with PBS, and resuspended in RIPA lysis buffer and 4% protease inhibitor on ice for 30 minutes. Samples were then centrifuged at 16,000 g for 30 minutes at 4°C and the protein concentration was determined using Bradford assay (DC Protein Assay kit, Bio-Rad Laboratories, Hercules, CA). Telomerase activity was assessed as described previously and according to the manufacturer's instructions.

#### 6.12 Quantitative Reverse Transcription PCR (RT-qPCR)

In CTH cells, the detection of absolute mRNA levels of epidermal growth factor receptor (EGFR), cyclin dependent kinase inhibitor 2A (CNDK2A), cyclin D1 (CCND1), SOX2, Oct4, and Nanog was assessed by RT-qPCR. Furthermore, RT-qPCR was also used to detect the transcripts of IE1, UL69, Myc, EZH2, OLIG2, CD133, SOX2, CD44, EGFR, MET, HCMV lncRNA4.9, and cellular lncRNA HOTAIR in CEGBCs as well as the IE1, UL69, EZH2, Myc, Sox2, Nanog, and Oct4 transcripts in CTO cells. RT-qPCR was performed as detailed previously [126,356]. In brief, RNA was extracted from the biopsies or the aforementioned cells using the EZNA® Total RNA Kit I (Omega BIO-TEK, Norcross, GA, USA). Reverse transcription was carried out using the SuperScript IV First-Strand Synthesis kit (Invitrogen, Carlsbad, CA, USA). The expression of markers was assessed by performing real-time qPCR using a KAPA SYBR FAST Master mix (KAPA BIOSYSTEMS, KK4601) and specific primers according to the manufacturer's protocol. The fold change expression was calculated by adopting the delta-delta Ct method [356].

#### 6.13 Invasion Assay

Collagen invasion assay: Collagen I (Corning, New York, NY) of 1 mg/ml concentration was prepared in 1X PBS with 7.2mM NaOH and 0.1% HCl was added. Where indicated, treatments, were mixed directly into the collagen gels. Prepared spheroids were incubated on ice for 30 min and then separately selected, washed in PBS, and subsequently included in the collagen solution.

After 1 hour at 37°C in a cell incubator, serum-free astrocytes medium including the diverse treatments was added. Secondly, 3D astrocyte scaffold invasion assay: scaffolds were formed by HAs in hyperconfluent culture. Afterwards, CEGBCs-DB and BL spheroids were cultured on top of HAs scaffolds. Spheroids' core area and invasion area were measured using ImageJ software; protrusions were measured using OPTIKA Vision Pro software and manually quantified.

#### 6.14 Treatments

Where indicated, CTH cells were treated with ganciclovir (GCV) and paclitaxel (PTX). CEGBCs-DB and BL were under GCV, temozolomide (TMZ), and EZH2 inhibitor (GSK343). Treatments was renewed every day. Further, CTO-DB and BL were treated with the two EZH2 inhibitors (GSK343 and EPZ6438). Treatment was renewed every 2 days. CTH, CEGBCs, and CTO cells were also treated with 12-O-45 tetradecanoylphorbol-13-acetate (TPA); treatment was renewed daily. The dosages corresponding to each drug were provided in **Table 6**.

#### 6.15 Tumor Biopsies and HCMV isolation

##### 6.15.1 Tumor Biopsies

All tumor biopsies were provided by the Regional tumor bank (BB0033-00024 Tumorothèque Régionale de Franche-Comté). It's worth noting that a written informed consent for participation was obtained from all patients. The studies were authorized by the local ethics committees of Besançon University Hospital (Besançon, France) and the French Research Ministry (AC-2015-2496, CNIL n°1173545, NF-S-138 96900 n°F2015).

-Tumor breast biopsies (luminal tumor biopsies n=10 and basal tumor biopsies n=9) and adjacent healthy breast biopsies (n=8). The treatment, clinical outcome and pathological data for these two TNBC patients were described previously [126].

-GBM biopsies [n=37; O (6)-methylguanine DNA methyltransferase (MGMT) promoter methylated GBM biopsies n=17, and MGMT promoter unmethylated GBM biopsies n=20] as well as healthy brain biopsies (n=4). Clinical and biological data of the GBM patients were provided in **Table 7**.

**Table 7: Clinical and biological data of the GBM patients.**

GBM Patients N°	Age (years)	Sex (F/M)	CMV detection (IE1/UL69 Expression)	EZH2 Fold gene Expression (Low/Intermediate/ High)	Myc Fold gene Expression (Low/Intermediate/ High)	Akt Fold gene Expression (Low/Intermediate/ High)

### 6.15.2 Genes and Transcripts Expression As Well As Polyploidy Detection Within Tumor Biopsies

RNA was extracted from TNBC biopsies (B544 and B693) followed by reverse transcription to measure EGFR, CNDK2A, CCND1, SOX2, Oct4, and Nanog mRNA expression by RT-qPCR. Genomic DNA was isolated from GBM as well as OC biopsies, and HCMV presence was identified by qPCR using specific primers against IE1 and UL69 genes. Further, RNA was extracted from GBM and OC biopsies and reverse transcription was performed as reported previously. For GBM biopsies, expression of EZH2, Myc, Akt, and GAPDH was assessed by real-time qPCR using specific primers according to the manufacturer's protocol. For OC biopsies, the expression of EZH2, Myc, Akt, and  $\beta$ -2-Microglobulin was assessed by real-time qPCR using specific primers according to the manufacturer's protocol. Fold change expression in TNBC, GBM and OC biopsies versus healthy breast and brain biopsies as well as adjacent non-tumoral OC biopsies, respectively was calculated using the delta-delta Ct method.

In TNBC biopsies, hematoxylin and eosin slides were used to detect PGCCs presence based on Zhang et al. description, with PGCCs being defined as a cancer cell with a nucleus at least three times larger than that of a diploid cancer cell [115]. PGCCs presence in HGSOC biopsies was confirmed by hematoxylin and eosin staining; briefly, PGCCs were counted in five hot spots of each tumor sample (magnification x400, field diameter of 250  $\mu$ m and 100  $\mu$ m, Zeiss Axiostar).

### 6.15.3 HCMV Isolation From Tumor Biopsies

HCMV strains, B544 and B693, were isolated from TNBC patient biopsies by mechanical tissue disruption and filtration of the frozen biopsy through a 0.45  $\mu$ m filter and initially grown on MRC5 cells. The supernatant from MRC5 culture was filtrated through a 0.45  $\mu$ m filter and used to infect HMECs. The purity of our HCMV cultures was confirmed by ruling out the presence of other viruses (Epstein-Barr virus, human papillomavirus, Kaposi sarcoma herpesvirus and adenovirus). Eleven HCMV-GBM strains were isolated from MGMT promoter methylated (n=4) and promoter unmethylated (n=7) GBM biopsies by mechanical tissue disruption and filtration of the frozen biopsy through a 0.45  $\mu$ m filter and initially grown on MRC5 cells. The supernatant from MRC5 culture was used to infect fresh human astrocytes. The purity of our HCMV cultures was confirmed by ruling out the presence of other viruses (Epstein-Barr virus and human papillomavirus). Three

HCMV-OC strains were isolated from HGSOC biopsies. Neither human papillomavirus (HPV) nor Epstein-Barr virus (EBV) was detected in the OC biopsies.

#### 6.16 Statistical Analyses

All quantitative results are reported as mean  $\pm$  SD of the independent experiments. Statistical analyses were done using Wilcoxon and Mann-Whitney tests; a p-value  $\leq 0.05$  was considered to be statistically significant [\* :  $\leq 0.05$ ; \*\* :  $\leq 0.01$ ; \*\*\* :  $\leq 0.001$ ]. Correlation analyses were done using Spearman, Pearson, and Kendall's Tau correlation tests. Microsoft Excel was used to construct the plots and histogram data.

## Chapter 7

### 7. Results

#### 7.1 Oncogenic and Stemness Signatures of the High-Risk HCMV Strains in Breast Cancer Progression

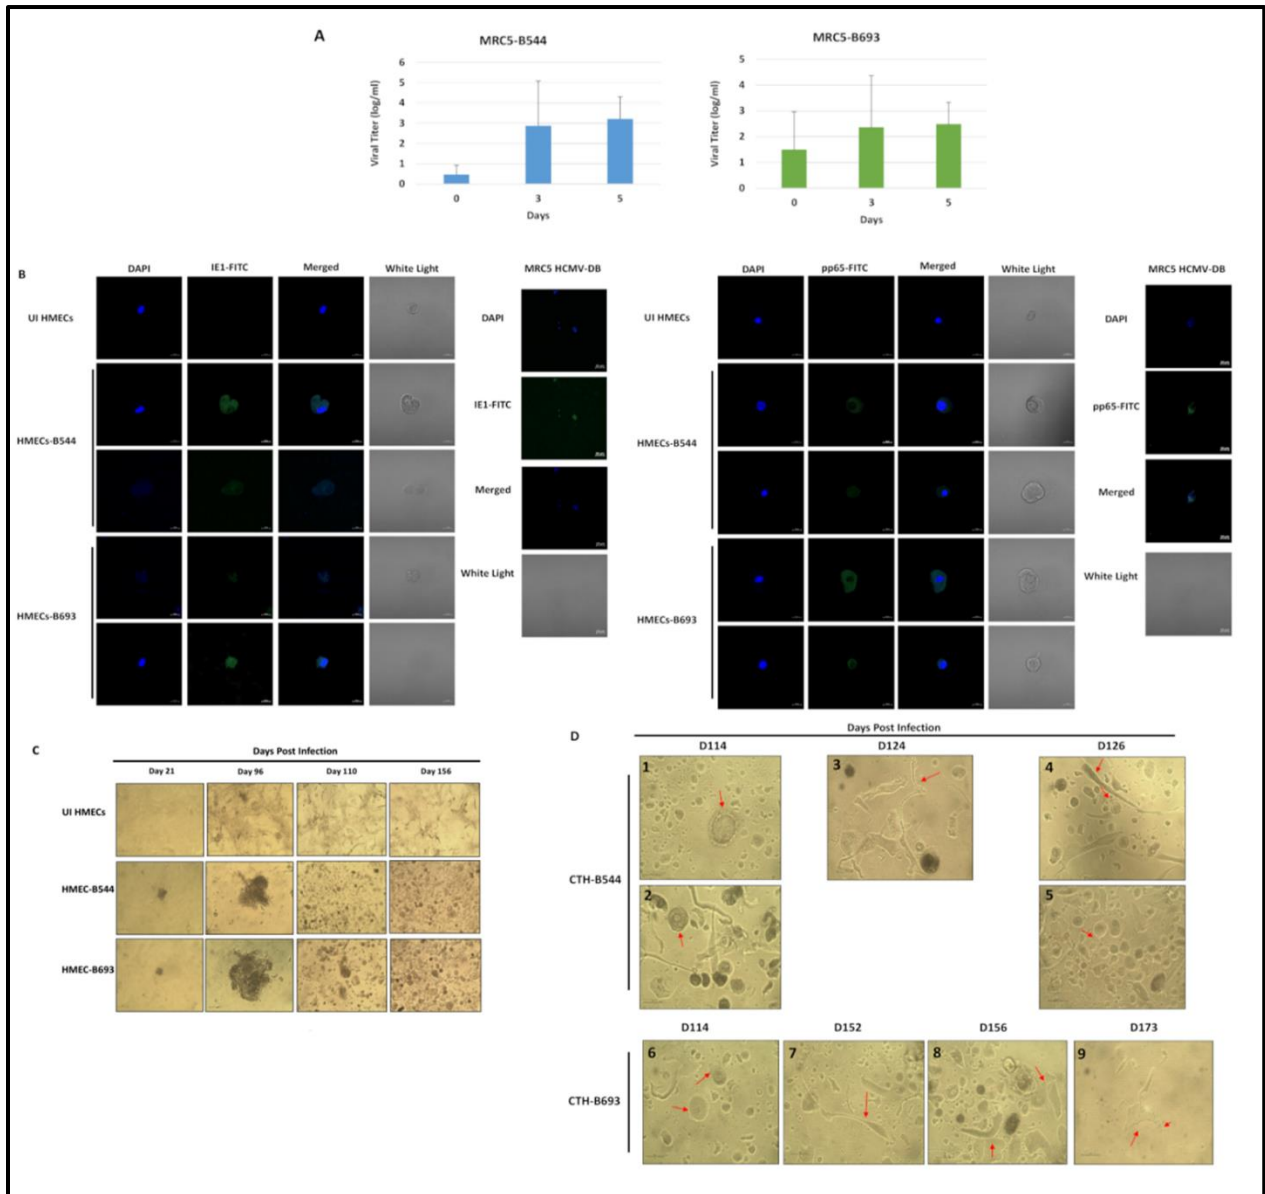

##### 7.1.1 Growth of Two HCMV Clinical Strains Isolated from TNBC in HMECs and the Emergence of Morphologically Distinct Cells

To assess the cellular environment achieved by HCMV, B544 and B693 were isolated from TNBC biopsies and grown in MRC5 cells, revealing a viral growth at days 3 and 5 post-infection (PI) (**Figure 10A**). At day 1 post-HMECs infection, HCMV-IE1 and pp65 were detected with confocal microscopy (**Figure 10B**). HCMV-B544 and B693 promoted the transformation of the infected HMECs toward CTH cells as previously reported [126]. Uninfected HMECs were used as controls which underwent cellular senescence in long-term cultures. At day 110 PI, we detected a wide variety of spheroids and giant cells distributed between round dense cells, flat, and elongated spindle-like cells. Afterwards, lipid droplet-packed cells, multinucleated giant cells, cell budding, and filopodium protrusions were observed in CTH cultures (**Figure 10C,D**). Hence, this population displayed mesenchymal and fibroblastic-like structures in addition to epithelial and small cells. The above-mentioned detailed cell morphology is close to that of CTH cells which were previously detected in HMEC cultures acutely infected with high-risk BL and DB strains [126]. Thus, the CTH-B544 and CTH-B693 heterogeneous cell population represent transformed and self-renewing cells that are engaged in distinct phases of the giant cell cycle [117,118].

##### 7.1.2 Transformation Capacity of CTH Cells and the Induction of an Oncogenic Environment

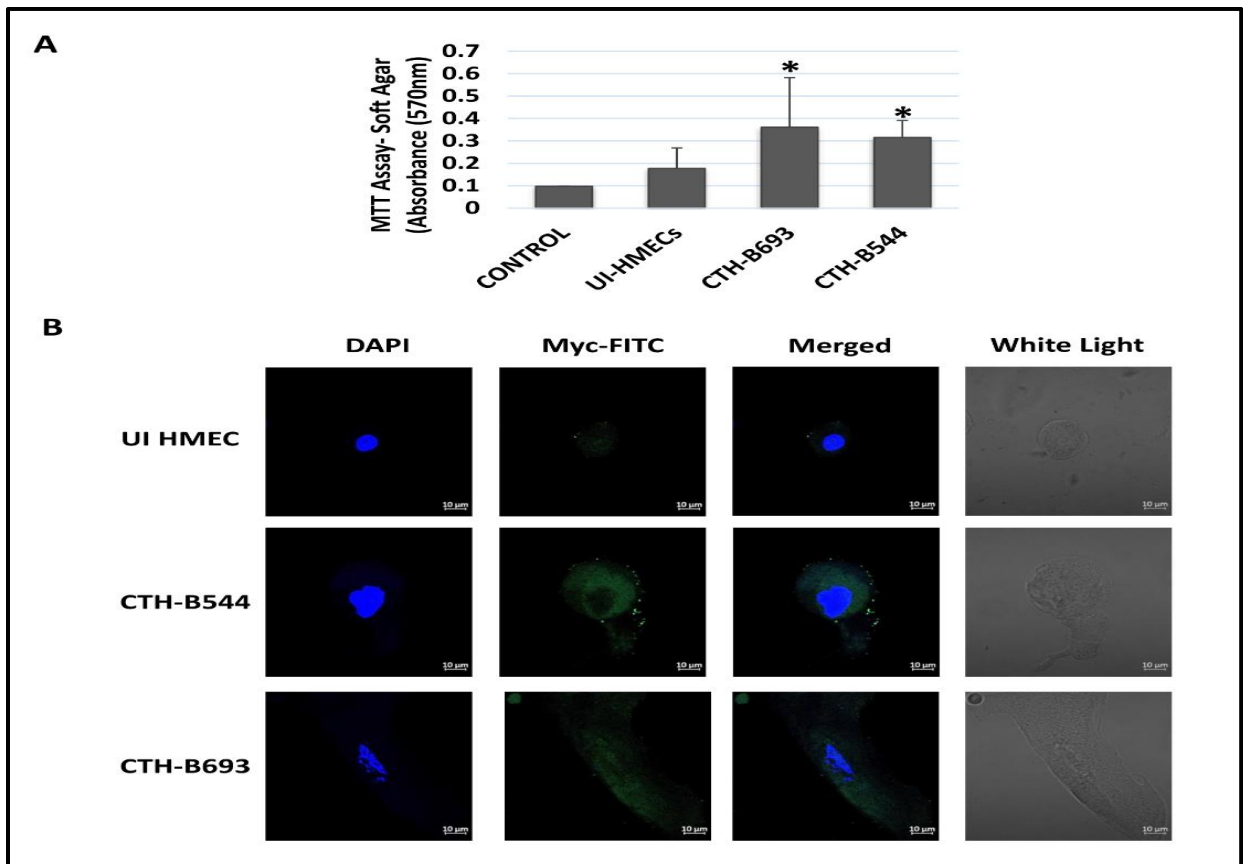

To evaluate the transformation of HCMV-B544 and B693 immortalized infected HMECs, cells were seeded in soft agar. Colony formation was detected at day 14 post-seeding in CTH-B544 and CTH-B693 cells ( $p$ -value  $\leq 0.05$ ) in contrast to uninfected HMECs which showed no changes (**Figure 11A**). The resulting anchorage-independent growth in CTH cells is a crucial phase in the acquisition of malignancies. With regard to oncogenes, the expression of c-Myc was assessed by performing confocal microscopy imaging where large and elongated CTH cells showed remarkable c-Myc staining compared to uninfected HMECs (**Figure 11B**). Using flow cytometry, a slightly higher expression of the proliferation marker (Ki67Ag) was detected in CTH-B693

compared to CTH-B544 cells with a limited expression in the uninfected HMECs. Only CTH-B544 and B693 cells were positively stained with Ki67 Ag as detected by confocal microscopy imaging (**Figure 12A**). On the other hand, a slight increase in the expression of phosphorylated Akt (pAkt-ser473) along with a limited to nonexistent increase in Akt expression levels was shown in all CTH cells compared to uninfected HMECs (**Figure 12B**). Overall, the acquisition of an immortal phenotype in CTH-B544 and B693 cells reflects their transformation potential.

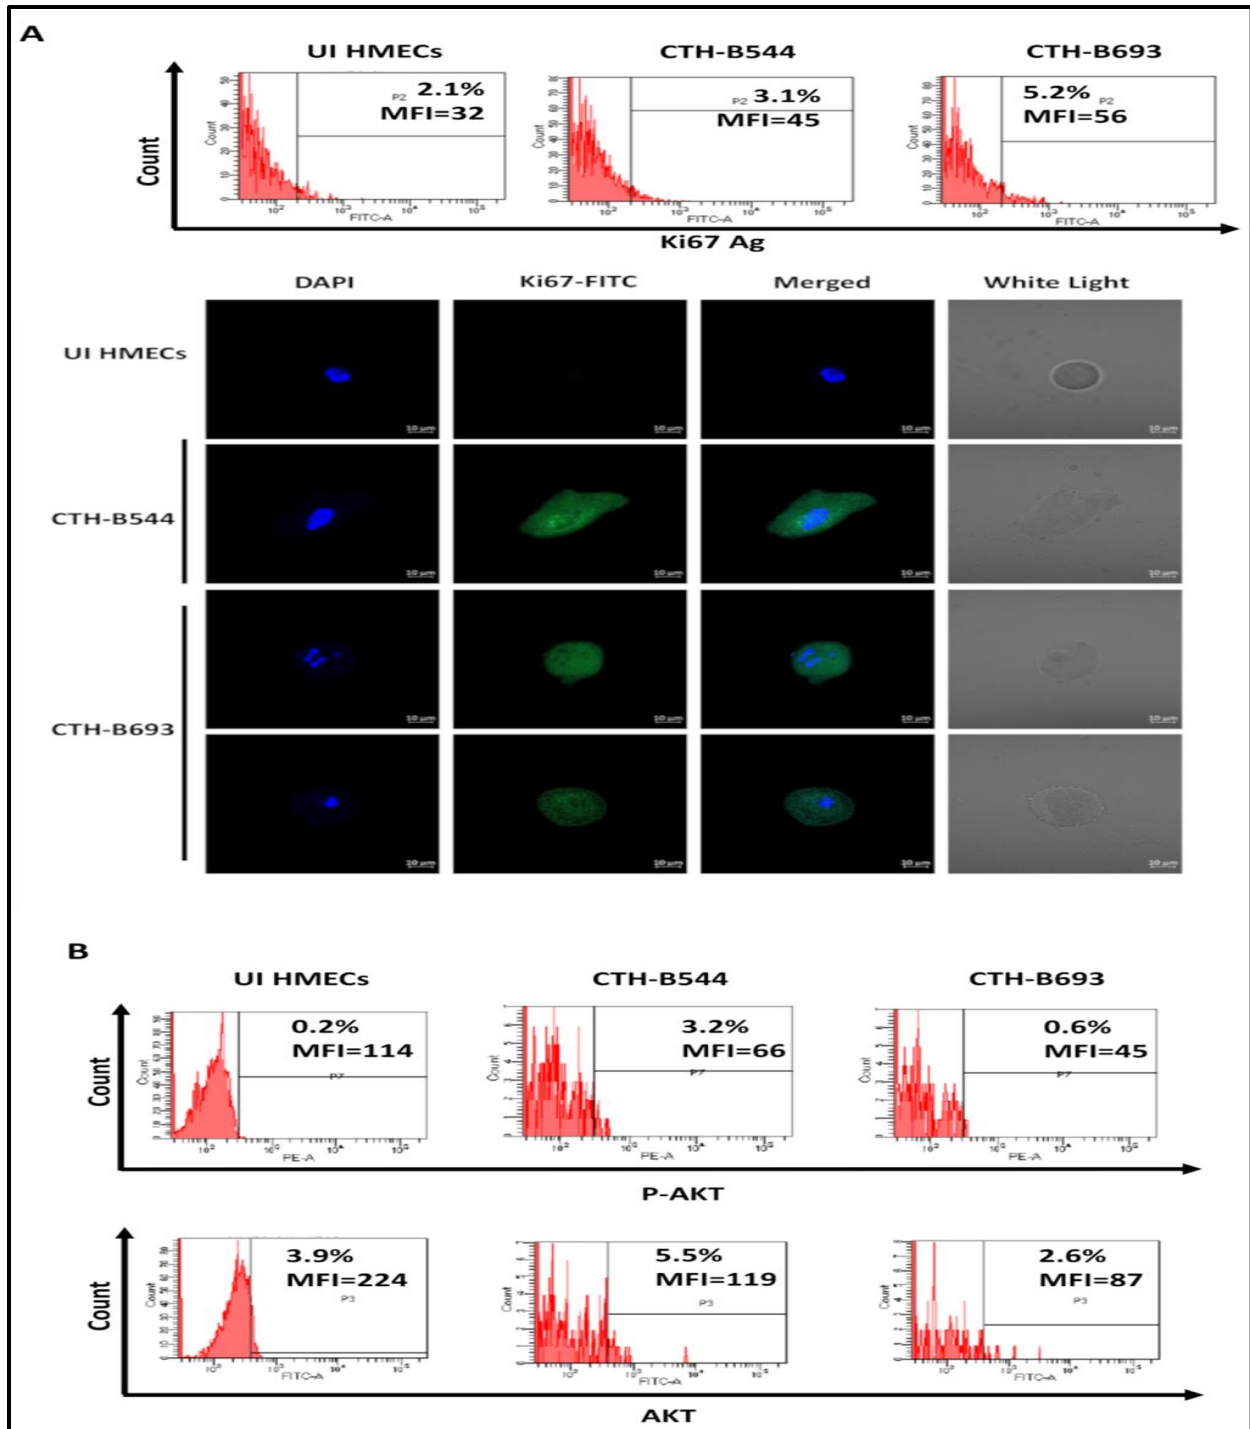

**Figure 10: Replication of B544 and B693 strains in MRC5 cultures, and the appearance of morphologically distinct cells following the infection of HMECs with these high-risk strains.**

(A) Time-course of the viral titer in the supernatant of MRC5 infected with the strains HCMV-B544 and HCMV-B693, as measured by IE1-qPCR. (B) Confocal microscopic images of HCMV-IE1 and pp65 staining in HMECs infected with HCMV-B544 and HCMV-B693 (day 1 post-infection). Uninfected HMECs were used as controls. Nuclei were counterstained with DAPI; magnification  $\times 63$ , scale bar 10  $\mu\text{m}$ . (C) HMECs time-course infection with HCMV-B544 and HCMV-B693 strains (MOI = 1). Magnification  $\times 100$ , scale bar 100  $\mu\text{m}$ . Uninfected HMECs were used as a control. (D) Presence of giant cells with blastomere-like morphology (1 and 6), mesenchymal cells (4 and 7), lipid droplet-packed cells (3, 8, and 9), cells displaying multiple nuclei (2) as well as cell budding (4, 5, and 6), and cells with filopodia protrusions (9) in CTH-B544 and CTH-B693 cells. The inverted light microscope scale bar represents 100  $\mu\text{m}$ ; magnification  $\times 200$ .

**Figure 11: Colony formation in soft agar and Myc expression in CTH-B544 and B693 cells.**

(A) Colony formation in soft agar seeded with uninfected HMECs, CTH-B544 and CTH-B693 cells. At day 15 post-seeding, quantification of colonies was performed; Histogram represents the mean data  $\pm$  SD of three independent experiments. \* p-value  $\leq 0.05$ , (B) Confocal microscopic images of Myc and DAPI staining in CTH cells. Magnification  $\times 63$ , scale bar 10  $\mu\text{m}$ .

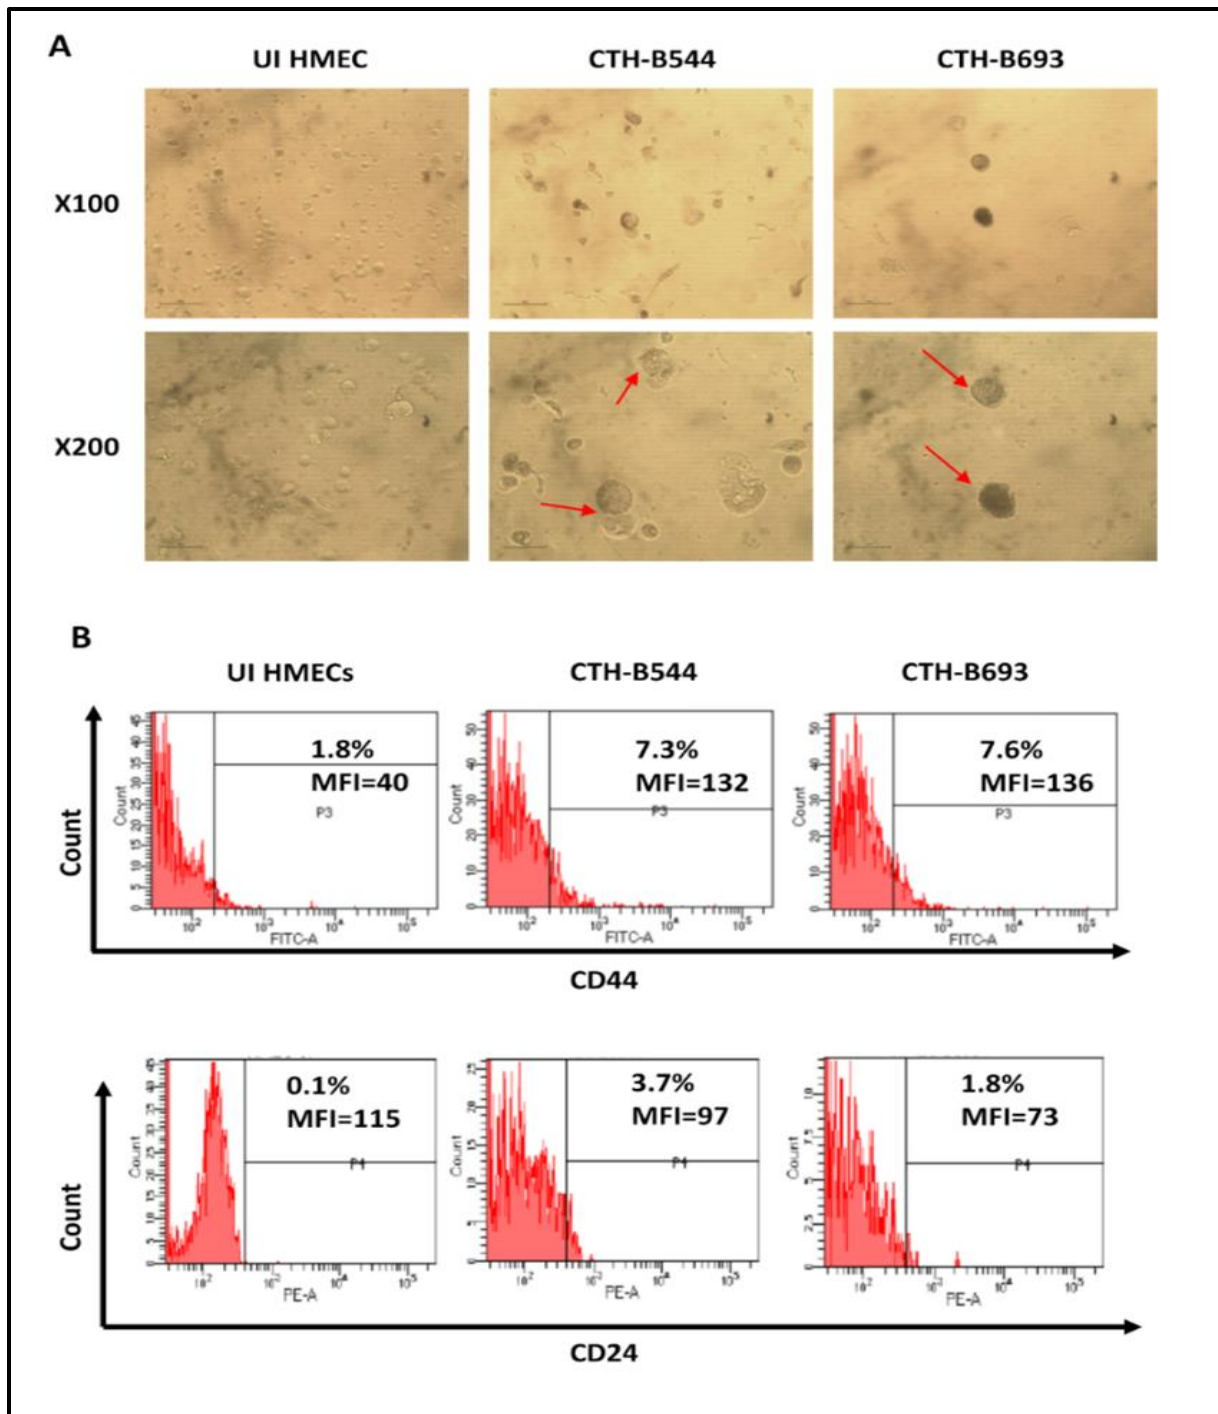

**Figure 12: CTH proliferation capacities and AKT activation.**

(A) Proliferation assessment by FACS and confocal microscopy; UI HMECs, CTH-B544 and CTH-B693 cells were stained for Ki67 Ag and DAPI. Magnification  $\times 63$ , scale bar 10  $\mu\text{m}$ . (B) P-AKT, and AKT expression in UI HMECs and CTH cells, as measured by FACS. Results are representative of three independent experiments.

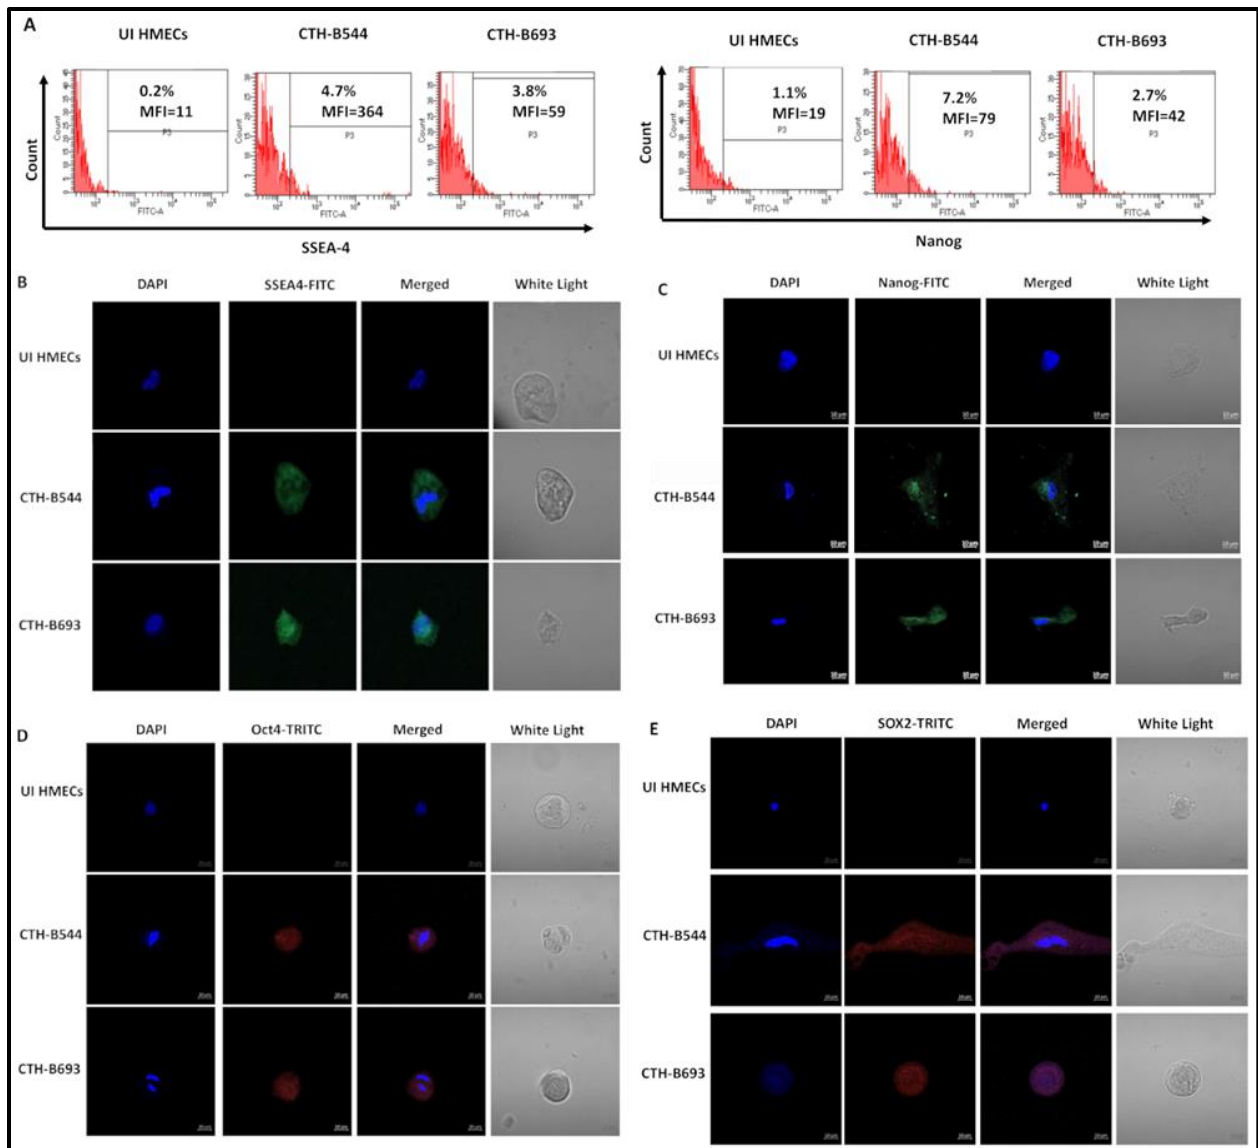

### 7.1.3 CTH Cells Promote Embryonic Stemness and Develop an Epithelial/Mesenchymal Hybrid State

When cultured in serum-free tumorsphere medium, CTH-B544 and B693 cells gave rise to mammospheres at day 14 and expressed stemness markers versus uninfected HMECs (**Figure 13A**). CTH cells revealed a rise in CD44 and CD24 expression when compared to uninfected HMECs (**Figure 13B**), in line with CTH-DB and BL data. Activated expression of the embryonic stem cell markers, SSEA-4 and Nanog, was recognized in CTH-B544, CTH-B693, CTH-DB, and CTH-BL cells by performing flow cytometry (**Figure 14A**) and confocal microscopy imaging (**Figure 14B,C**). Moreover, CTH-B544 and B693 cells gained embryonic stem-like properties by highly expressing Oct4 and SOX2 as demonstrated by confocal microscopy imaging (**Figure 14D,E**). Similar to CTH-DB and BL, the newly discovered CTH cells showed an elevated expression of the stemness marker CD49f or Integrin alpha-6, and a limited EpCAM expression (**Figure 15**). CTH-B544 and B693 as well as CTH-DB and BL cells were positive for both vimentin and E-cadherin staining (**Figure 15**) thereby signifying their ability to dynamically oscillate between the epithelial-hybrid-mesenchymal spectrum as reported previously in tumors with poor prognosis [367,368]. As a result, CTH-B544 and B693 cells exhibited the following two phenotypes: stemness and hybrid epithelial/mesenchymal phenotypes.

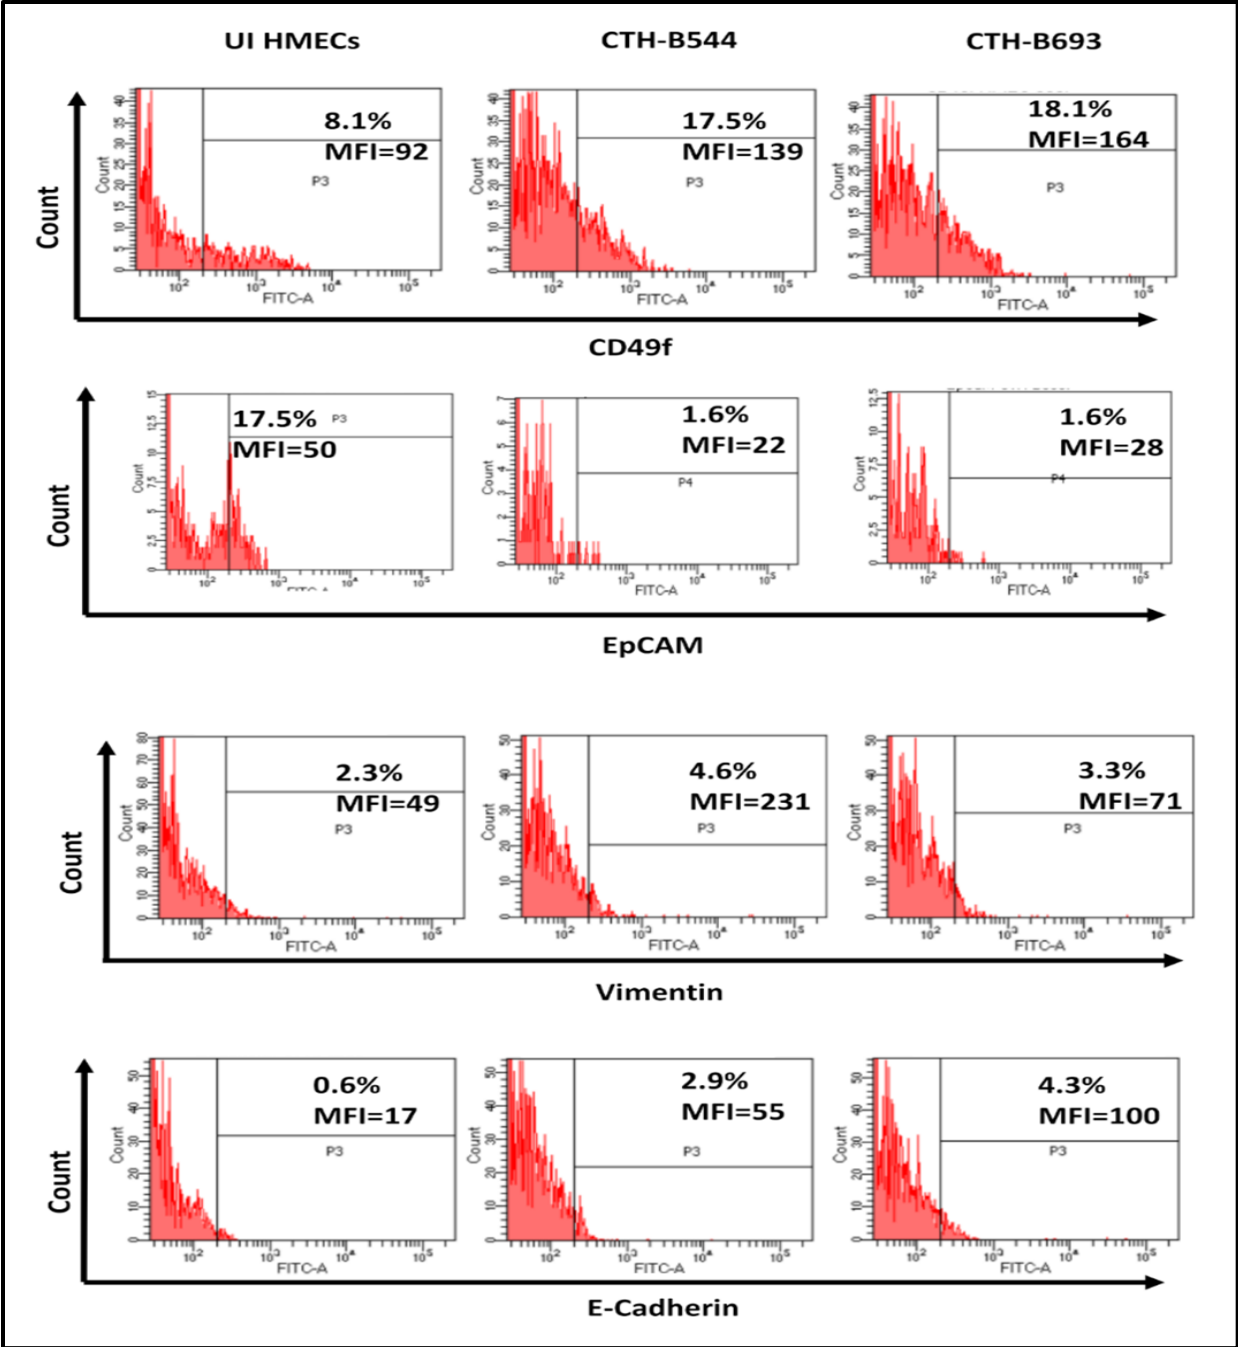

**Figure 13: Tumorspheres formation and the expression of stemness markers in CTH cells.**

(A) Tumorspheres were observed under an inverted light microscope in CTH-B544 and CTH-B693 cells. Magnification  $\times 100$  and  $\times 200$ , scale bare 100  $\mu\text{m}$ . Uninfected HMECs were used as a negative control. (B) FACS staining of CD44 and CD24 was performed in CTH cells. Results are representative of three independent experiments.

**Figure 14: Expression of embryonic stem cell markers in CTH-B544 and B693 cells.**

(A) Detection of SSEA4 and Nanog in CTH cells by FACS. Results are representative of three independent experiments. Confocal microscopy imaging demonstrating the expression of (B) SSEA-4, (C) Nanog, (D) Oct4, and (E) SOX2. Nuclei were counterstained with DAPI; magnification  $\times 63$ , scale bar 10  $\mu\text{m}$ .

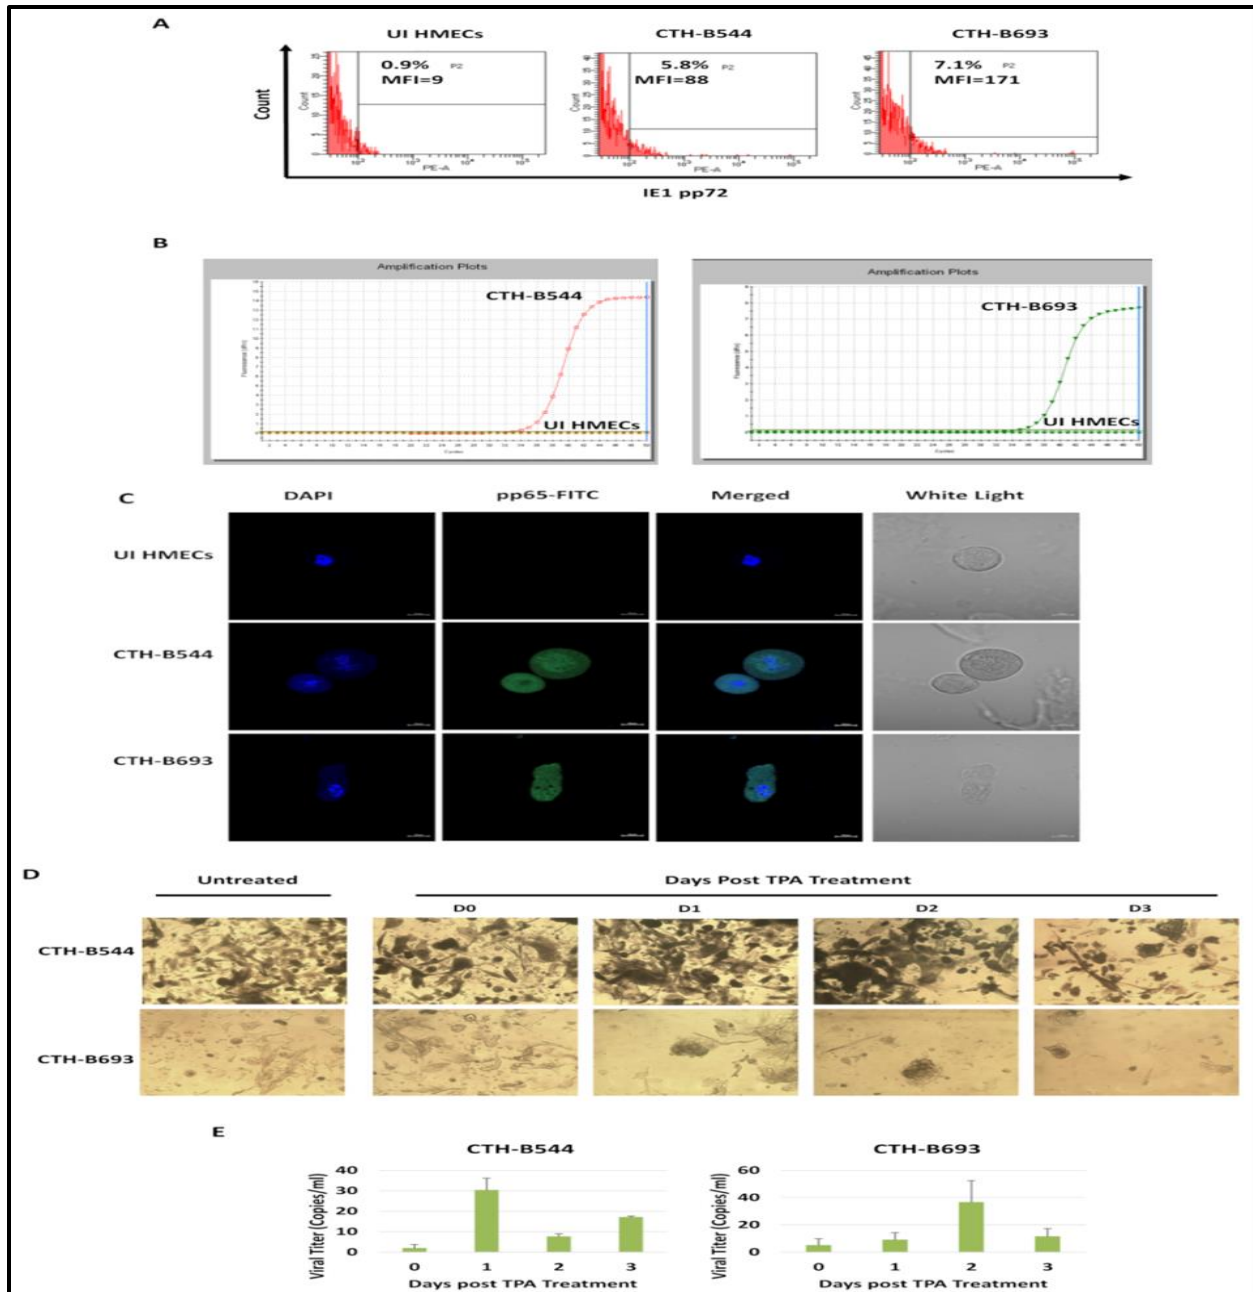

**Figure 15: Phenotypic analysis of CTH cells.**

Detection of a panel of cell markers through FACS staining of CD49f, EpCAM, Vimentin, and E-cadherin in CTH-B544 and CTH-B693 versus UI HMECs. Results are representative of three independent experiments.

#### 7.1.4 Persistent HCMV Replication in CTH-B544 and CTH-B693 Long-Term Cultures

To determine the sustained HCMV presence, HCMV-IE1 antigen was detected using flow cytometric analysis. IE1 was strongly expressed in CTH-B544 and CTH-B693; uninfected HMECs showed no staining for IE1 (**Figure 16A**). Using qPCR, we detected HCMV (IE1 DNA) in the supernatant of CTH-B544 and CTH-B693 cultures (**Figure 16B**). Further, CTH cells were positively stained for HCMV-pp65 antigen versus uninfected HMECs (**Figure 16C**). CTH cells were treated with TPA to assess latency relevance (**Figure 16D,E**). Post TPA treatment, the proliferation of CTH-B544 and CTH-B693 cells was promoted (**Figure 16D**). IE1 detection was elevated at day 1 and day 2 post-treatment in CTH-B544 and CTH-B693, respectively ( $p$ -value= 0.33), and subsequently decreased (**Figure 16E**).

**Figure 16: Sustained viral replication in CTH cells.**

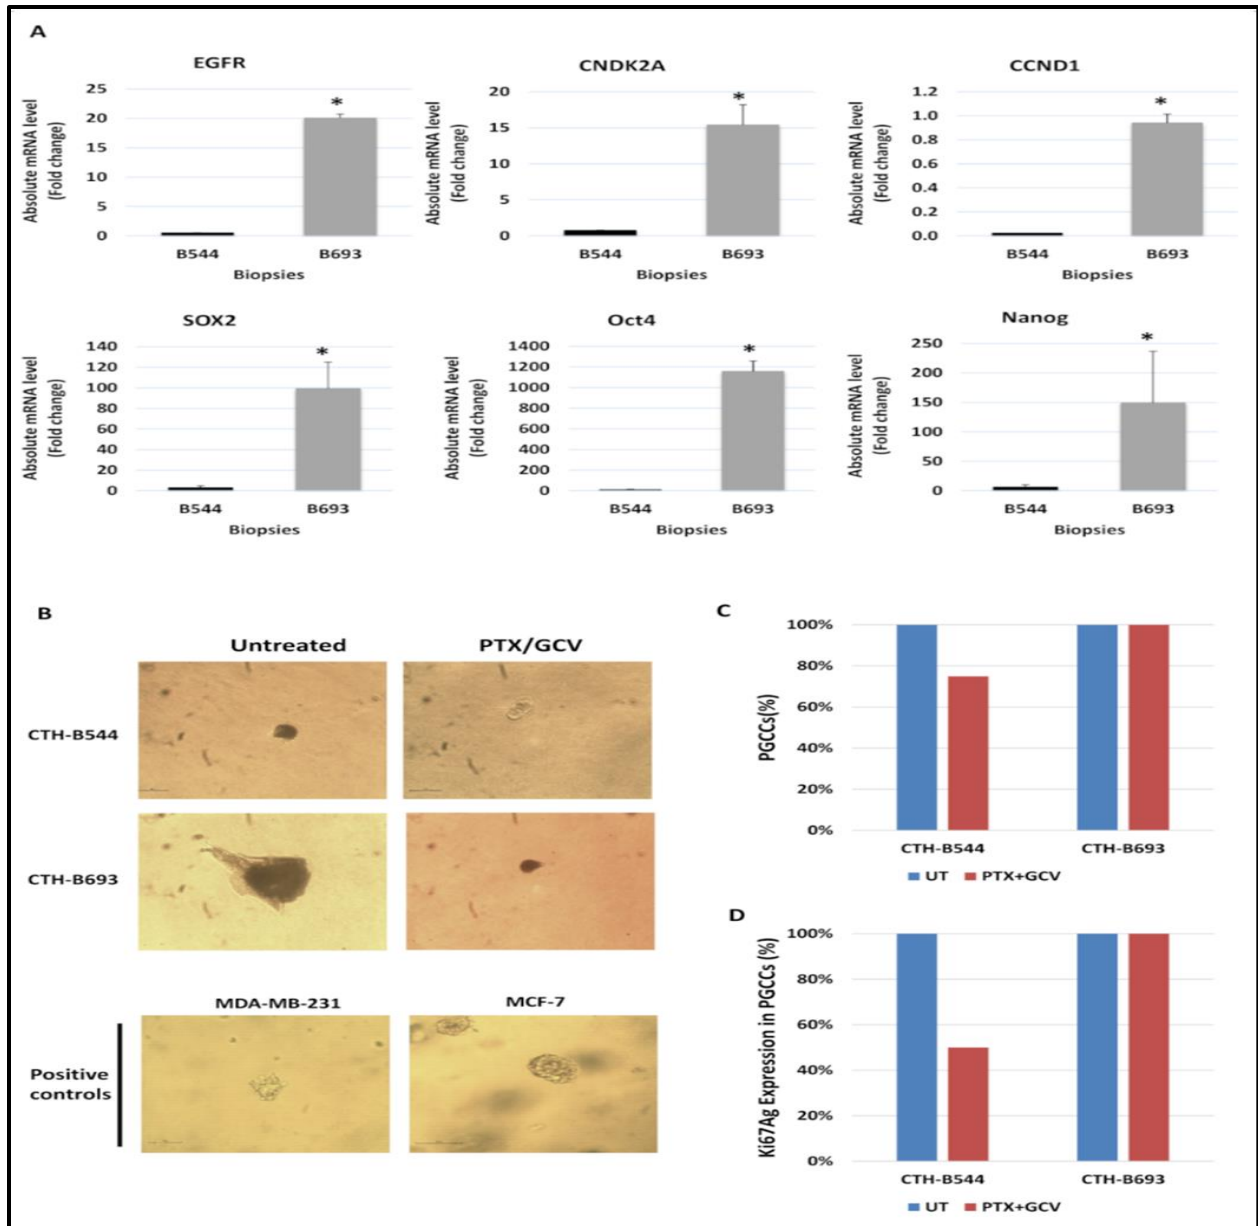

IE1 expression in CTH cells was assessed by (A) FACS and (B) qPCR. (C) pp65 detection in CTH-B544 and B693 cells as demonstrated by confocal microscopy imaging. As a negative control, uninfected HMECs were used; nuclei were counterstained with DAPI; magnification  $\times 63$ , scale bar 10  $\mu\text{m}$ . (D, E) Determination of viral reactivation from latency in CTH cells through the treatment of TPA. (D) Representative images of CTH cultures treated with TPA (100 nM). Untreated cells were used as a control. Magnification  $\times 100$ , scale bar 100  $\mu\text{m}$ . (E) HCMV lytic replication was induced by TPA in CTH cultures. Histograms represent the mean data  $\pm$  SD of three independent experiments.

### 7.1.5 A Specific Molecular Landscape Unveiled in the Tumor Microenvironment of TNBC Harboring High-Risk HCMV

To evaluate the variation in strains' aggressiveness, we compared the transcriptomic profile corresponding to the two high-risk biopsies. The absolute mRNA level of epidermal growth factor receptor (EGFR), cyclin dependent kinase inhibitor 2A (CNDK2A), cyclin D1 (CCND1), SOX2, Oct4, and Nanog was assessed by RT-qPCR. EGFR, a proto-oncogene that enhances cell proliferation and survival, the cell cycle regulator CNDK2A, the proliferation marker CCND1, and the three embryonic markers were overexpressed in biopsy 693 compared to biopsy 544 ( $p$ -value  $\leq 0.05$  for all markers) (**Figure 17A**). Our results indicated that biopsy 693, from which we isolated the HCMV-B693 strain, is associated with higher tumor aggressiveness and poor prognosis.

### 7.1.6 Restricting Soft Agar Colony Formation, Controlling PGCCs Count and Proliferation by Paclitaxel and Ganciclovir Therapy

To assess the colony formation in soft agar, CTH cells were treated by PTX/GCV combination therapy to target the oncogenic cellular environment as well as HCMV. Breast cancer cell lines, MDAMB231 and MCF7 were used as positive controls. PTX/GCV treatment of CTH-B544 cells resulted in the disappearance of colonies; however, colony formation was restricted in treated CTH-B693 cells versus untreated cells (**Figure 17B**). Post therapy, the PGCCs count was reduced by 25% in CTH-B544 while it remained constant in CTH-B693 as measured by FACS (**Figure 17C**). Further, the proliferation of PGCCs was assessed by Ki67 Ag measurement using flow cytometric analysis; Ki67 Ag expression was reduced in PTX/GCV-treated CTH-B544, but not in CTH-B693 (**Figure 17D**). Our outcomes revealed that CTH-B544 cells are more responsive to PTX/GCV therapy compared to CTH-B693 cells implying that the latter exhibits aggressive behavior.

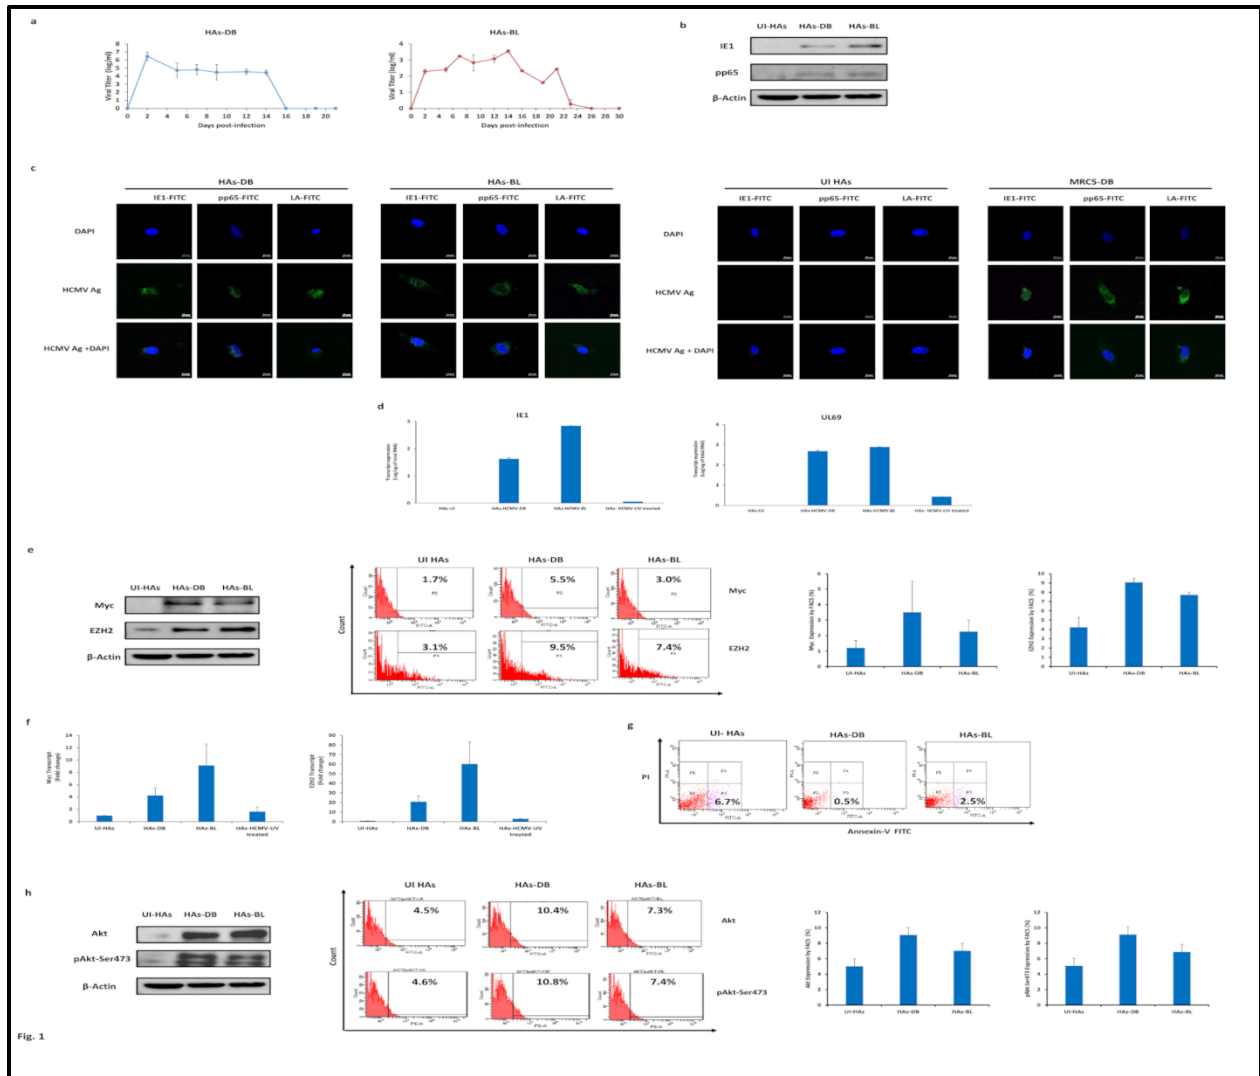

**Figure 17: Distinct responses of CTH cells to paclitaxel/ganciclovir (PTX/GCV) treatment in vitro recapitulates distinct TNBC molecular signatures in vivo.**

(A) EGFR, CNDK2A, CCND1, SOX2, Oct4, and Nanog mRNA expression was measured by RT-qPCR in TNBC biopsies B544 and B693. Histograms represent the mean  $\pm$  SD of three independent experiments. \*  $p \leq 0.05$ , determined by Mann–Whitney U test. (B) Soft agar seeded with CTH-B544 and CTH-B693 cells treated with PTX (20 nM)/GCV (20  $\mu$ M) combination therapy. Untreated cells were used as negative controls; MCF7 and MDA-MB231 cells were used as positive controls. Magnification  $\times 200$ , scale bar 100  $\mu$ m. (C) Propidium iodide (PI) staining for detection of PGCCs in untreated and treated CTH cells by FACS analysis. (D) Ki67 Ag expression in PGCCs of untreated and treated CTH cells. Histograms represent the mean data  $\pm$  SD of three independent experiments.

## 7.2 EZH2-Myc Driven Glioblastoma Elicited by Cytomegalovirus Infection of Human Astrocytes

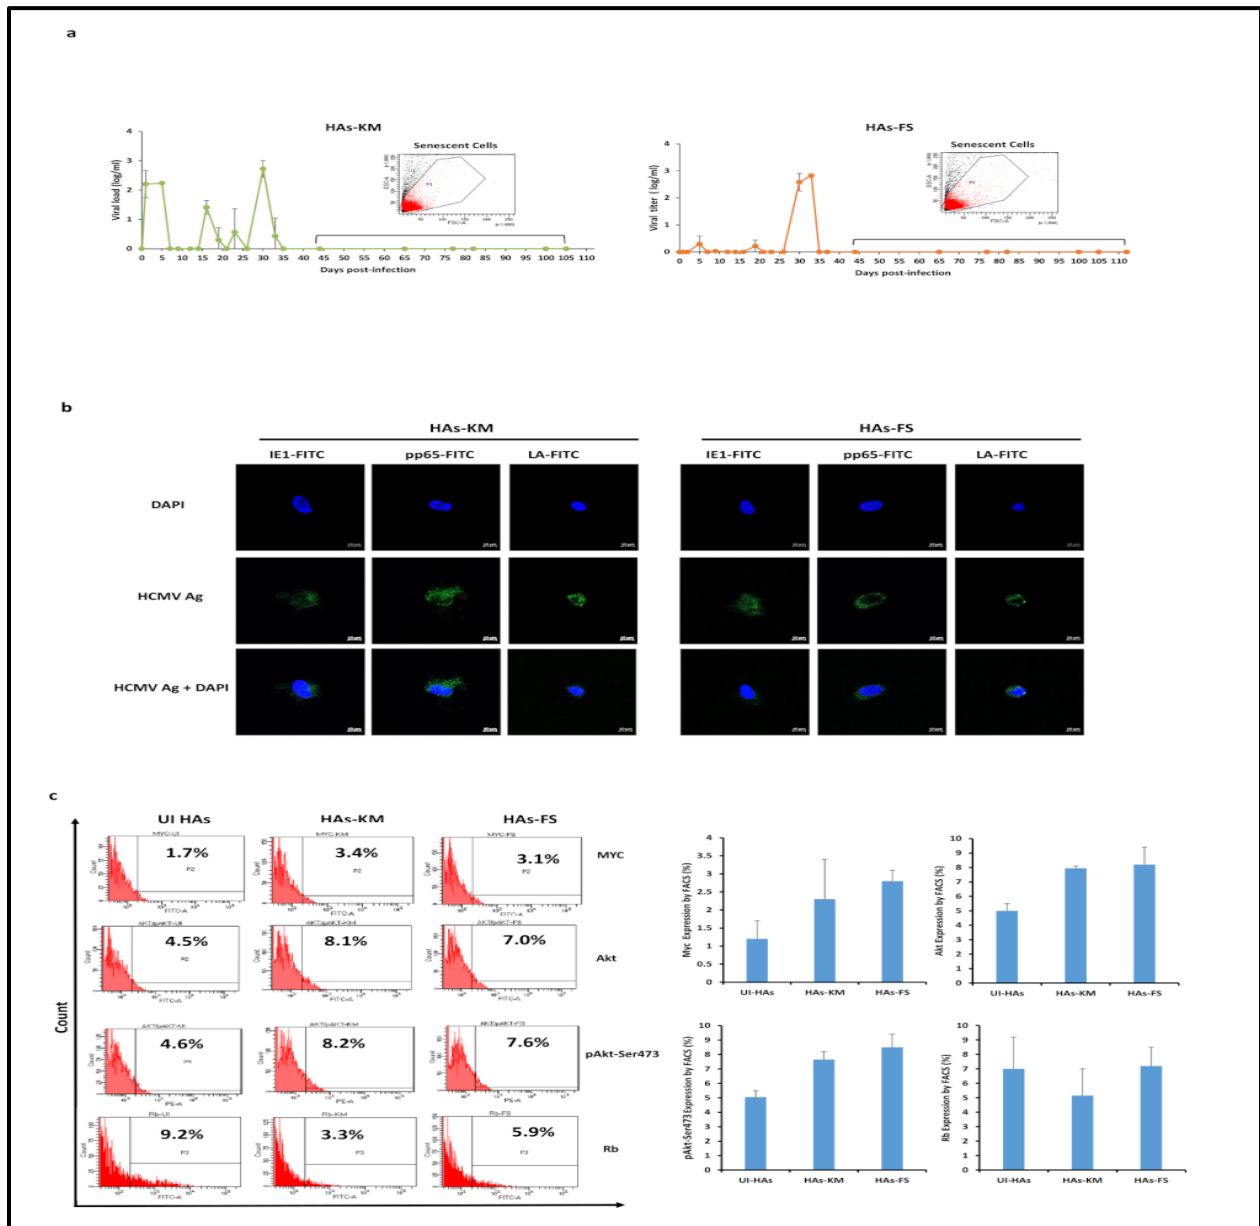

### 7.2.1 HCMV Clinical Isolates Permissively Infect HAs Inducing Increased Myc and EZH2 Expression

The cellular environment induced by HCMV infection was assessed by studying the tropism of DB and BL high-risk HCMV strains (**Figure 18**) as well as KM and FS low-risk HCMV strains (**Figure 19**) to HAs. HCMV-DB and BL strains replicated in HAs with a burst of viral growth (6 logs for DB and 3 logs for BL) followed by occasional blips (**Figure 18A and Figure 20**). Acute infection was then confirmed through immediate early gene (IE1), pp65, and the late HCMV antigens detection (**Figure 18B,C and Figure 19**). In addition, IE1 and early/late gene (UL69) transcripts were detected in HAs infected with HCMV-DB and BL compared to controls (**Figure 18D**). At day 3 post-infection, Myc was overexpressed in HAs-DB and BL compared to controls ( $p$ -value = 0.09), mostly in HAs-DB. Elevated EZH2 expression was detected in HAs-DB and BL compared to uninfected HAs ( $p$ -value = 0.02) (**Figure 18E**). Myc and EZH2 transcripts were detected in HAs-DB and BL compared to controls (**Figure 18F**). Lower apoptosis levels were recognized with the two strains (**Figure 18G**) in line with Akt and pAkt-Ser473 upregulation as confirmed by western blot and FACS, particularly with HCMV-DB (**Figure 18H**). In contrast to the high-risk DB and BL strains, the low-risk FS and KM strains did not elicit any of the above-mentioned behavior (**Figure 19**). Taken together, a Myc<sup>High</sup> EZH2<sup>High</sup> molecular profile was observed with both high-risk strains, preferentially with HCMV-DB.

**Figure 18: Replication of two high-risk oncogenic HCMV strains in HAS cultures, the activation of oncogenic pathways, and reduced apoptosis rates.**

(A) Time-course of the viral titer in the supernatant of HAS infected with HCMV-DB and BL as measured by IE1-qPCR. (B) Immunoblotting data of IE1 and pp65 in uninfected HAS lysates and HAS infected with HCMV-DB and BL (day 5 post-infection).  $\beta$ -actin was used as loading control. (C) Confocal microscopic images of HCMV-IE1, pp65, and late antigen staining in HAS infected with HCMV-DB and BL (day 1 post-infection). Uninfected HAS and MRC5- $\Gamma^D$  cells were used as negative and positive controls, respectively. Nuclei were counterstained with DAPI; magnification  $\times 63$ , scale bar 10  $\mu$ m. (D) IE1 and UL69 transcripts detection by RT-qPCR in uninfected HAS, HAS-DB and BL as well as HAS infected with UV-treated HCMV. (E) Myc and EZH2 protein expression as measured by western blot (day 5 post-infection) and FACS (day 3 post-infection) in uninfected HAS and HAS infected with HCMV-DB and BL.  $\beta$ -actin was used as loading control. (F) Myc and EZH2 transcripts detection by RT-qPCR. (G) Early apoptosis assessment in HAS-DB and BL (MOI = 1). UI-HAs were used as a control. (H) Akt, and pAkt-Ser473 protein expression as measured by western blot and FACS in uninfected HAS and HAS infected with HCMV-DB and BL.  $\beta$ -actin was used as loading control. Data are represented as mean  $\pm$  SD of two independent experiments.

**Figure 19: Long-term cultures of HAS infected with the two low-risk HCMV strains.**

(A) Time-course of the viral titer in the supernatant of infected HAS as measured by IE1-qPCR along with the cellular analysis of HAS-KM and FS based on their size (FSC) and granularity (SSC). (B) Confocal microscopic images of HCMV-IE1, pp65, and late antigen staining in HAS infected with HCMV-KM and FS (day 1 post-infection). Nuclei were counterstained with DAPI; magnification  $\times 63$ , scale bar 10  $\mu\text{m}$ . (C) Myc, Akt, pAkt-Ser473, and Rb protein expression as measured by FACS in uninfected HAS and HAS infected with HCMV-KM and FS. Data are represented as mean  $\pm$  SD of two independent experiments.

### 7.2.2 Emergence of a Glioblastoma-Like Phenotype With CEGBCs in HAs Chronically Infected With High-Risk HCMV Strains.

In contrast to the low-risk HCMV strains that didn't allow long-term replication in HA cultures and were senescent (**Figure 19**), HAs infected with HCMV-DB and BL were maintained in culture for an extended period of time (**Figure 20**). Around day 80–90 post-infection, dense cellular aggregates appeared in HCMV-BL and DB cultures with invasive-like cells irradiating from the main cellular structures resembling the formerly described “go or growth” phenotype of glioblastoma cells [369] (**Figure 21A,B**). Cells with a glioblastoma-like phenotype were termed “*CMV-Elicited Glioblastoma Cells*” or CEGBCs similar to the previously reported “CMV-Transformed Human mammary epithelial cells” or CTH cells [125,209].

We next assessed the protein expression of EZH2 and Myc in CEGBCs in which increased expression levels were observed compared to controls (**Figure 21C**). CEGBCs characterization was achieved by assessing oncogenes, tumor suppressor genes and cell cycle genes. Oncogenes and cell cycle genes were mainly upregulated in CEGBCs-DB; however, tumor suppressor genes were down-regulated mostly in CEGBCs-BL (**Figure 21D,E**). CEGBCs-DB and BL were seeded on a soft agar to evaluate their tumorigenic potential and colony formation was detected; uninfected HAs and HAs infected with herpes simplex virus (HSV) showed no colony formation (**Figure 21F**). Primary GBM experiences the subtype switch during relapse, shifting from the proneural (PN) subtype to the mesenchymal (MES) one namely the proneural-mesenchymal transition (PMT), thus acquiring a therapy-resistant phenotype [370]. With regards to PMT markers, vimentin was elevated mostly in CEGBCs-DB, and to a lesser extent in CEGBCs-BL (**Figure 21G**). CD44, a widely accepted marker for cancer stem cells and a mesenchymal marker regulating both stemness and epithelial-mesenchymal plasticity, was shown to be predominantly upregulated in CEGBCs-DB (**Figure 21H**). EMT genes were mostly upregulated in CEGBCs-DB compared to CEGBCs-BL (**Figure 21I**). CEGBCs-DB were shown to be close to the transcriptome profile of mesenchymal glioblastoma (mGB) whereas CEGBCs-BL expressed more PN traits (mesenchymal markers:  $p$ -value<sub>(CEGBCs-DB:CEGBCs-BL)</sub> = 0.002; proneural markers:  $p$ -value<sub>(CEGBCs-DB:CEGBCs-BL)</sub> = 0.06) (**Figure 21J**). Taking into account the proteomic and transcriptome data, CEGBCs-DB mostly displayed a mesenchymal phenotype compared to

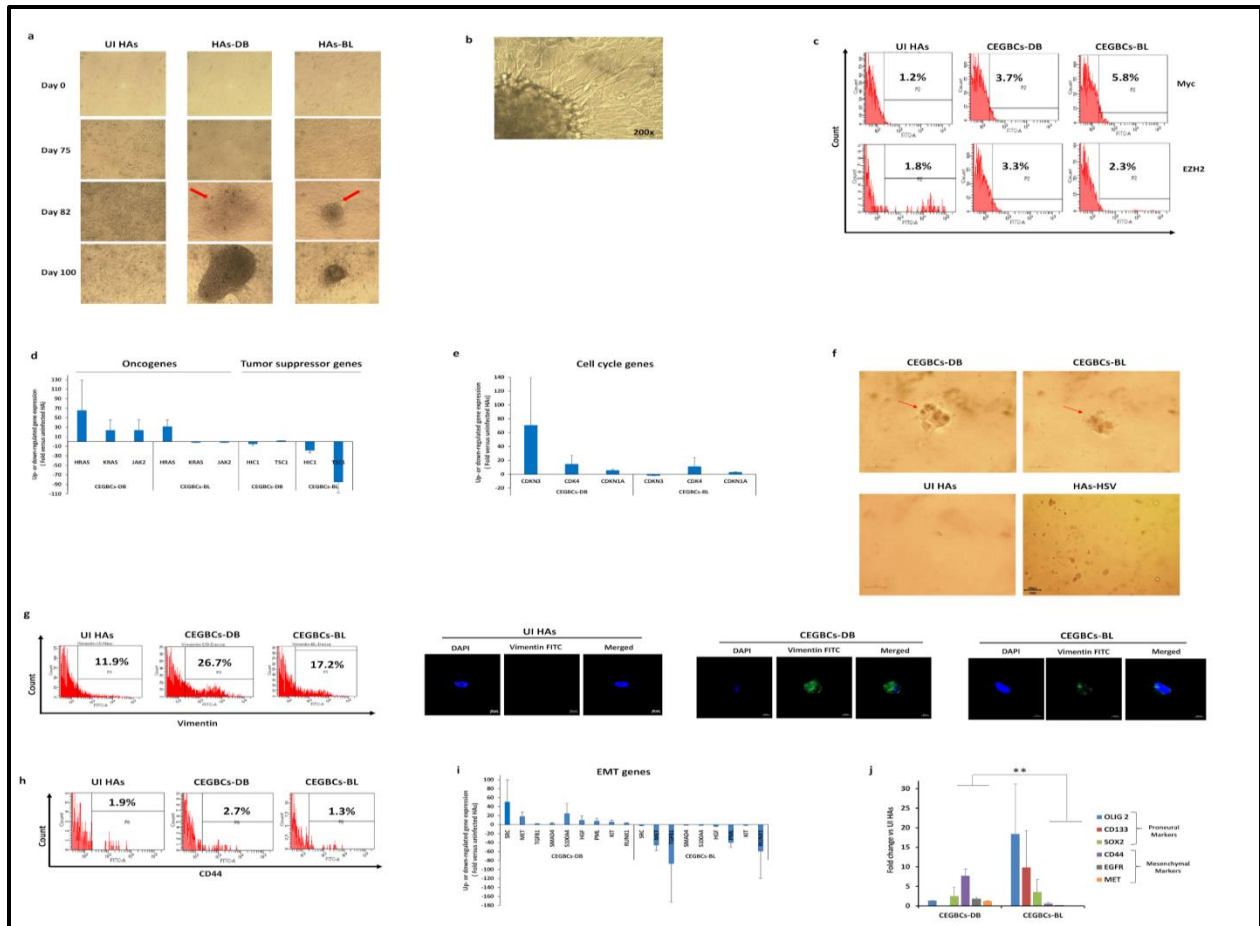

CEGBCs-BL. High levels of SOX2, Oct4, and SSEA4 were detected in CEGBCs (**Figure 22A and Figure 23A,B**). Hence, the identified stemness features in CEGBCs indicated their relevance to glioblastoma stem cells (GSCs). Assessing the spheroid formation potential of CEGBCs, spheroids were generated 24–48 hours post-seeding; no spheroid formation was detected in HAS infected with HSV (**Figure 22B**). Nestin and IE1 were concomitantly expressed in CEGBCs-DB and BL spheroids (**Figure 22C**).

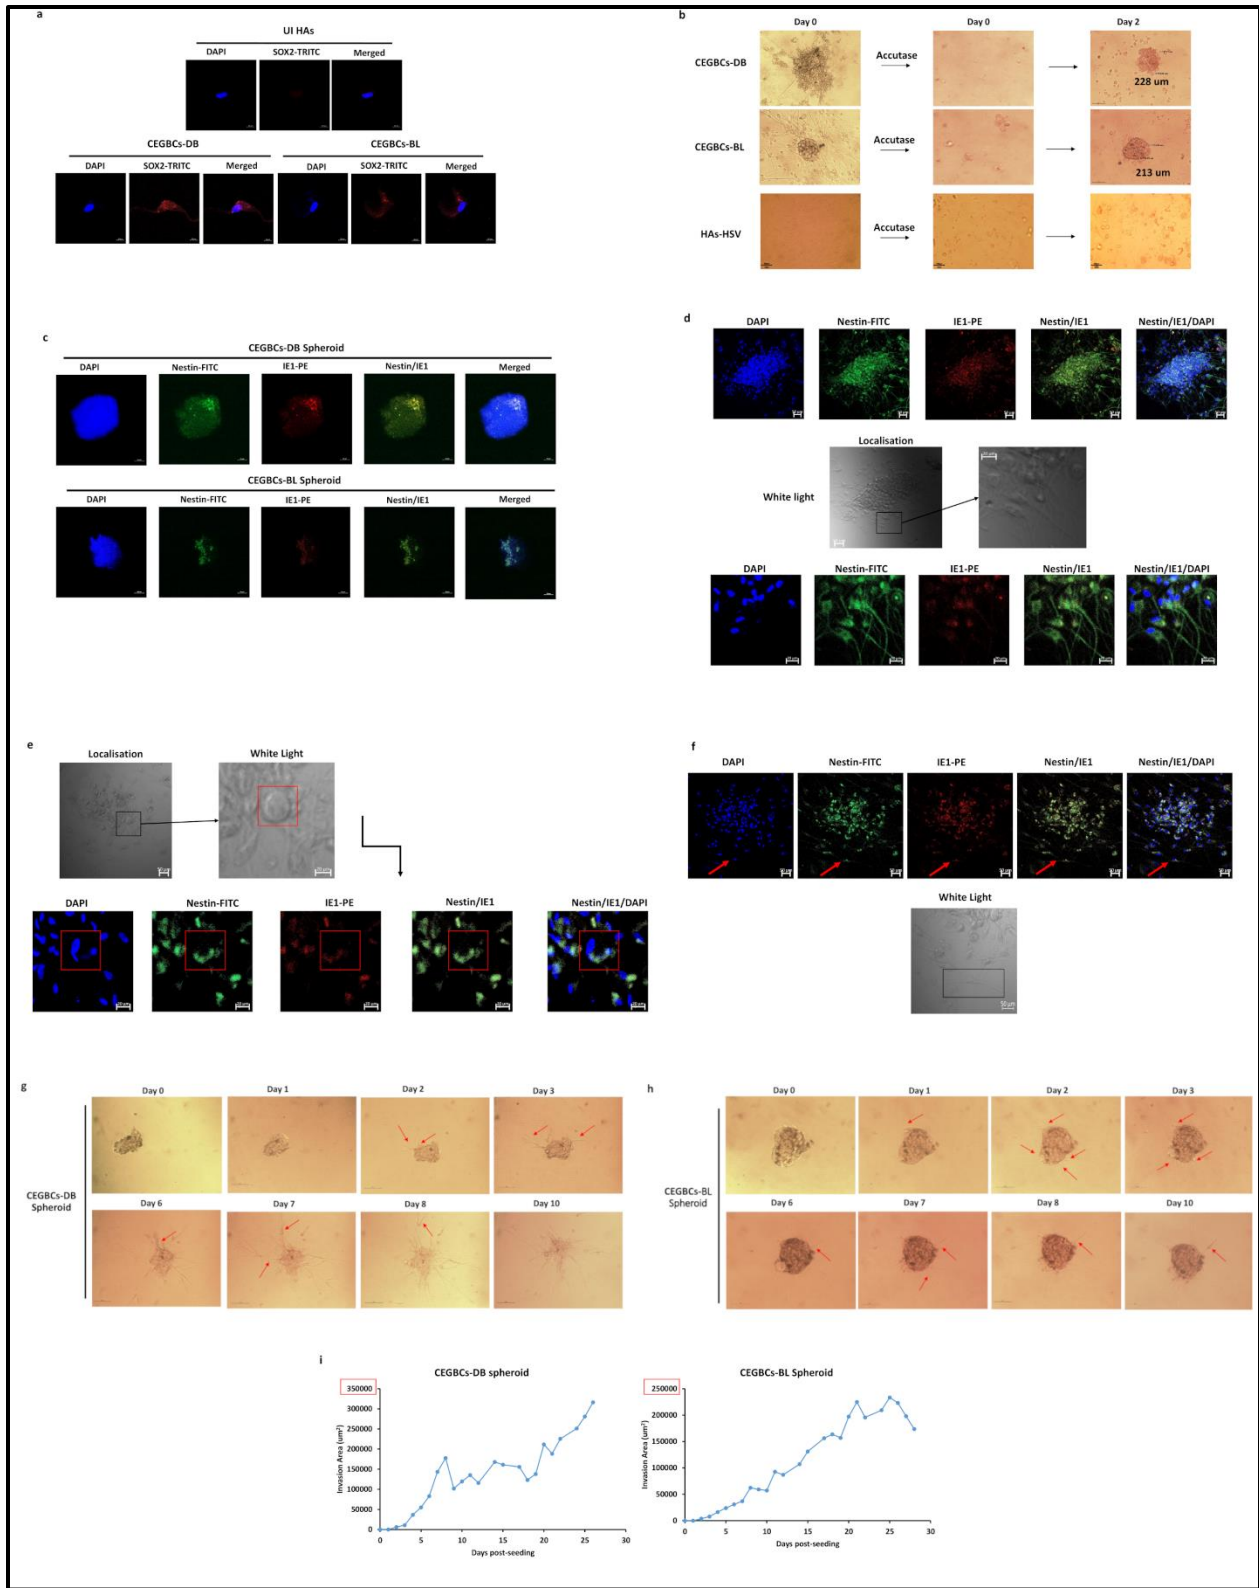

**Figure 20: Long-term replication of two high-risk HCMV strains in HAS cultures.**

Time-course of the viral titer in the supernatant of HAS infected with HCMV-DB and BL as measured by IE1-qPCR.

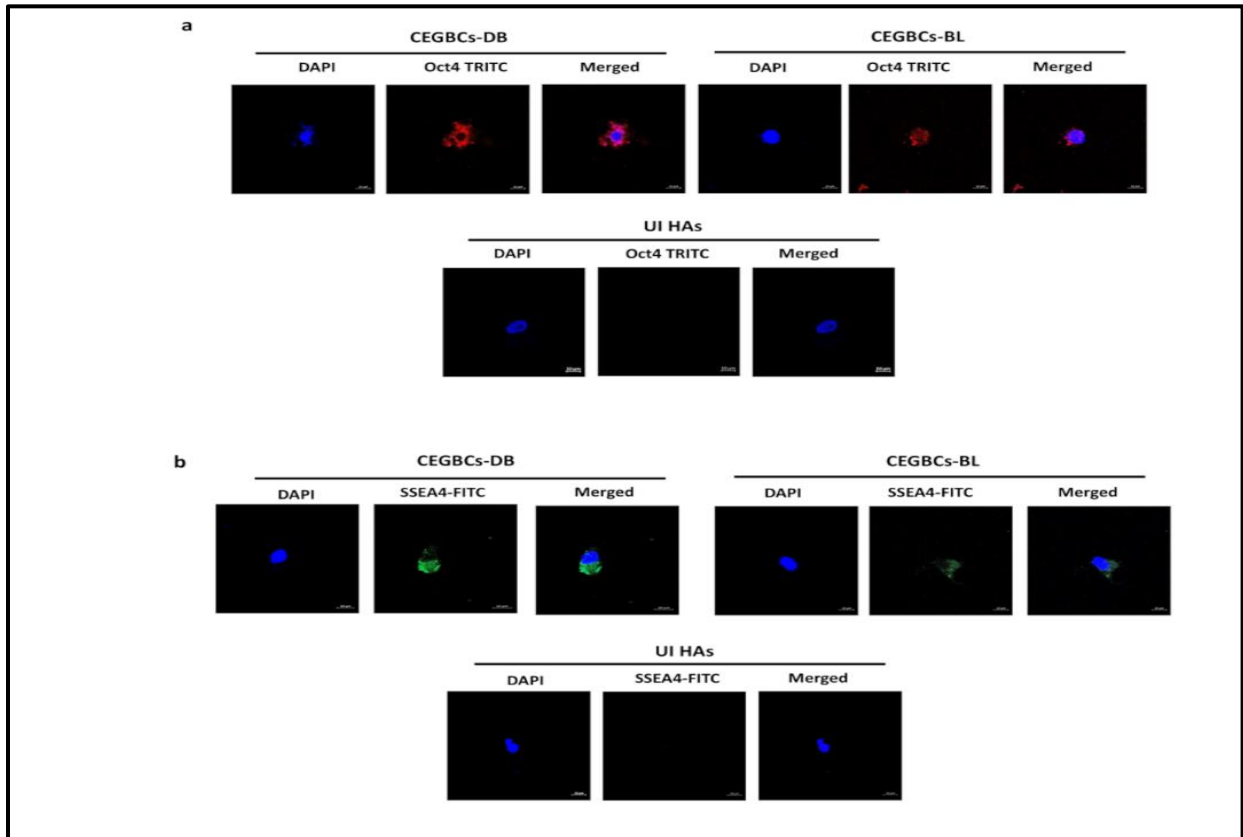

**Figure 21: Chronic infection of HAS with HCMV clinical isolates, the appearance of CEGBCs as well as colony formation in soft agar, and the phenotypic characterization of CEGBCs.**

(A) HAS time-course infection with HCMV-DB and BL strains (MOI = 1). Red arrows showing the generated CEGBCs. Magnification  $\times 100$ , scale bar 100  $\mu\text{m}$ . Uninfected HAS were used as a control. (B) An inverted light microscope was used to closely follow up the chronic CEGBCs-DB and BL cultures and the appearance of several structures; magnification 200x, scale bar 100  $\mu\text{m}$ . (C) FACS staining of Myc and EZH2 in HAS infected with HCMV-DB and BL; uninfected HAS were used as a negative control. The fold regulation of oncogenes and tumor suppressor genes (D) as well as cell cycle genes (E) was assessed in uninfected HAS and HAS infected with HCMV-DB and BL using RT2 Profiler PCR Arrays. (F) Colony formation in soft agar seeded with CEGBCs-DB and BL (MOI = 1); UI HAs and HAS-HSV were used as controls. Formed colonies were observed under an inverted light microscope (Magnification 200x, scale bar 100  $\mu\text{m}$ ). (G) Vimentin expression by FACS and confocal microscopy in CEGBCs-DB and BL; uninfected HAS were used as a control. Nuclei were counterstained with DAPI; magnification  $\times 63$ , scale bar 10  $\mu\text{m}$ . (H) FACS staining of CD44 in CEGBCs-DB and BL. Uninfected HAS were used as controls. (I) The fold regulation of EMT genes was assessed in UI HAs and HAS infected with HCMV-DB and BL using RT2 Profiler PCR Arrays. (J) Histogram depicting the expression of PN markers (OLIG2, CD133, and SOX2), MES markers (CD44, EGFR, and MET), as quantified by RT-qPCR in CEGBCs-DB and BL. \*\*p-value  $\leq 0.01$ . Data are represented as mean  $\pm$  SD of two independent experiments.

### 7.2.3 CEGBCs Productively Infected With High-Risk HCMV Display Invasiveness

CEGBCs from spheroids readily invaded astrocyte scaffolds, by aligning along and intercalating between astrocytes and penetrating all scaffold layers as measured by nestin detection. After 7 days, nestin was present in the spheroids' core and invasive part; cells were IE1 and nestin-positive. HCMV-IE1 was predominantly located in the spheroid core and present in the individual cells detaching from the core (**Figure 22D**). Uninfected HAs expressed GFAP in the absence of nestin. PGCCs and neural progenitor cell (NPC)-like cells, positive for nestin and IE1, were also present (**Figure 22E,F**); supernatants were positive for HCMV-IE1 indicating ongoing viral replication. Further, using a 3D collagen-invasion assay, invasiveness was noticed for CEGBCs-DB and to a lesser extent for CEGBCs-BL as measured by the invasion area (**Figure 22G,H**); the protrusions' number and length were also recorded (**Figure 24**). Within the CEGBCs-DB cultures, the majority of invading cells adopted a neural progenitor-like phenotype with a round small cell body and a long leading process characterized by high cell motility (**Figure 25, left panel**). Cellular heterogeneity occurred among the invasive cells with random morphology in which low motility cells co-existed with highly motile cells (**Figure 25**). Three mechanisms of invasiveness were detected in CEGBCs-DB and BL cultures as recently reported [371] (**Figure 26A,B, and C**). Filopodia and lamellipodia were also observed (**Figure 26D**).

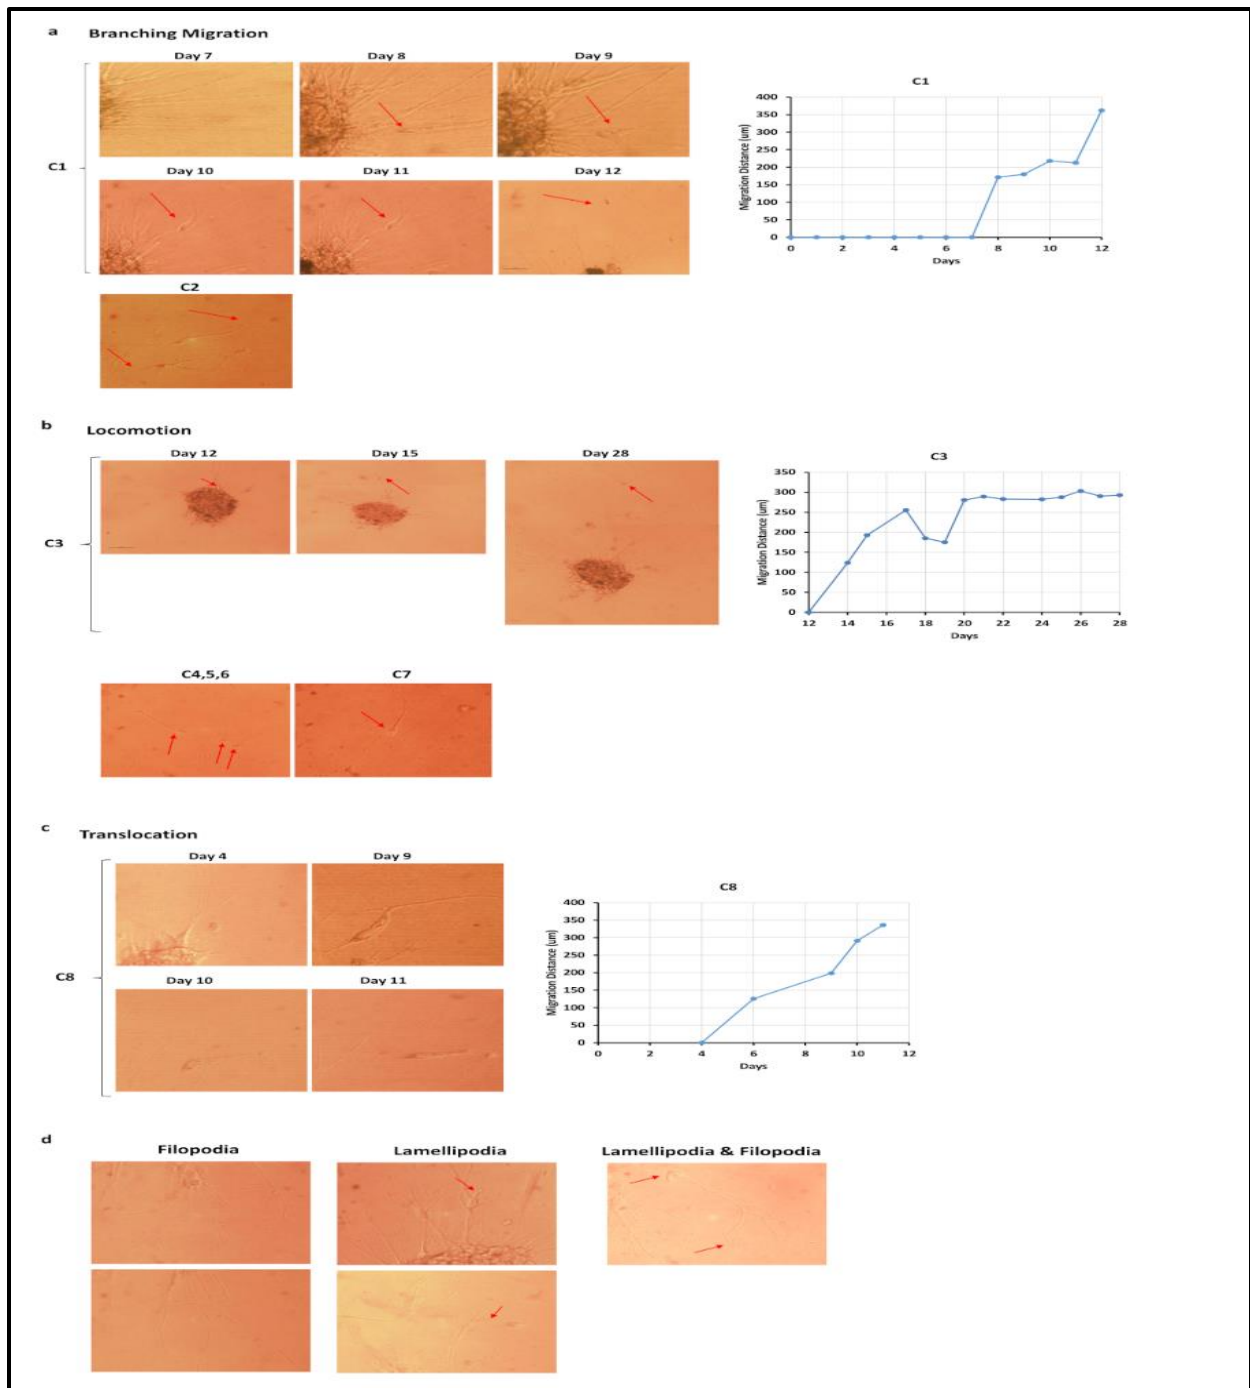

**Figure 24: The invasion capacities of CEGBCs-DB and BL.**

(A,B) Histograms representing the number (A) and size (B) of protrusions generated from CEGBCs-DB and BL spheroids. Data are represented as mean  $\pm$  SD of two independent experiments.

(D) Classification of specific structural features (filopodia and lamellipodia) of CEGBCs-DB and BL; magnification x100 and x200, scale bar 100µm.

#### 7.2.4 Detection of lncRNA4.9/EZH2 and HOTAIR/EZH2 Complexes in CEGBCs Cultures

HCMV latency in CEGBCs cultures was established by IE1 expression that was observed at day 1 post-TPA treatment (**Figure 27A**) parallel to the detection of HCMV gene (lncRNA4.9) (**Figure 27B**). In agreement with the presence of the lncRNA4.9 gene in EZH2-expressing CEGBCs, we observed the interaction of HCMV lncRNA4.9 and cellular lncRNA HOX antisense intergenic RNA (HOTAIR) transcripts with EZH2 using RNA CLIP assay (**Figure 27C,D**). Cellular lncRNA HOTAIR transcript, reported as a poor prognostic factor in cancers [372] was detected particularly in the EZH2 immunoprecipitated samples corresponding to CEGBCs-DB compared to CEGBCs-BL (**Figure 27D**).

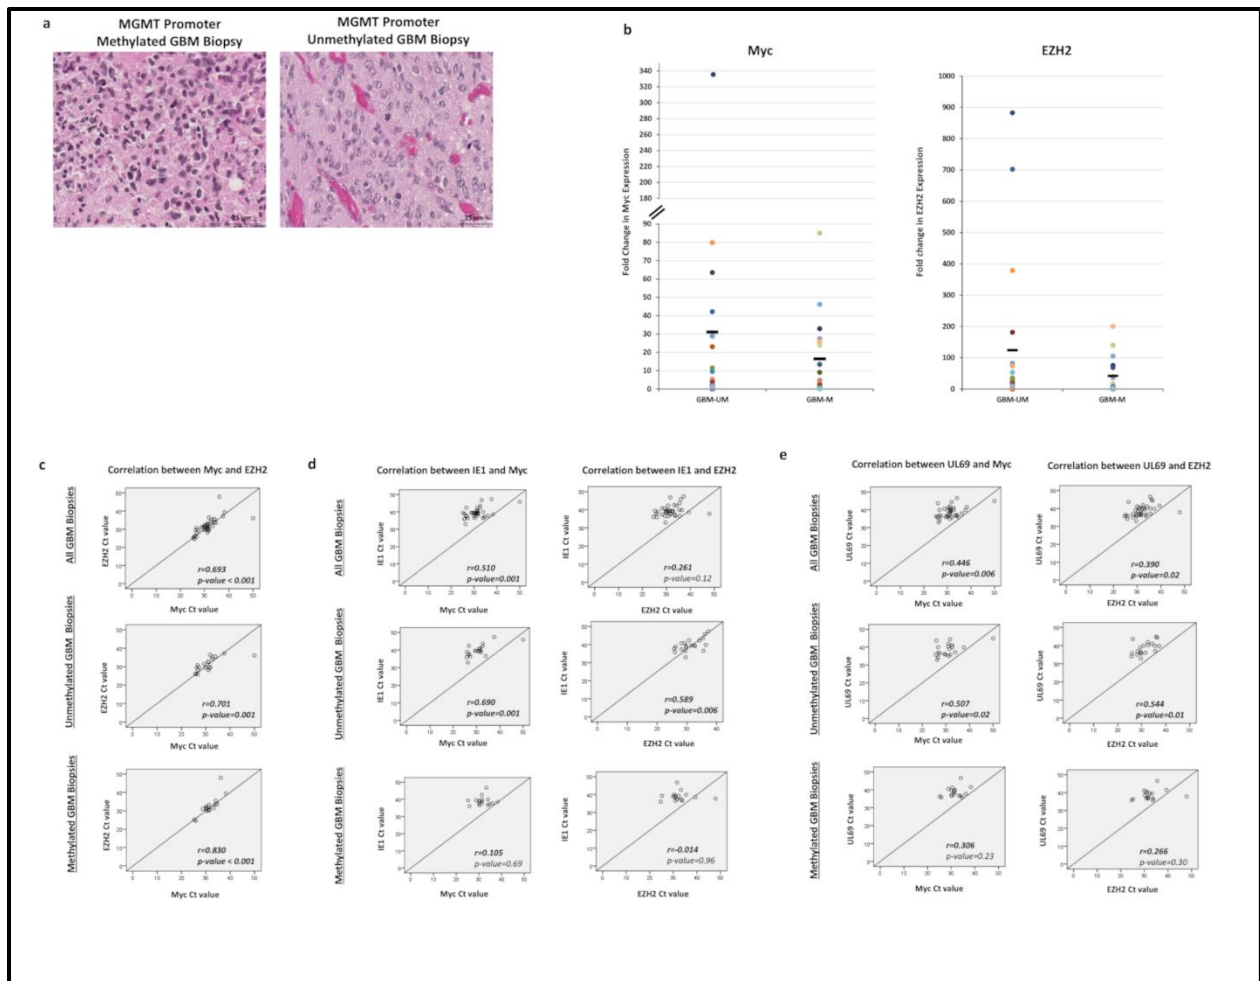

**Figure 27: Detection of replicative HCMV and identification of the lncRNA4.9 and HOTAIR/EZH2 complex in CEGBCs cultures.**

(A) Histograms representing the viral load post-TPA treatment (100 nM) in CEGBCs-DB and BL cultures as measured by IE1-qPCR. (B) lncRNA 4.9 gene detection in CEGBCs-DB and BL using RT-qPCR. HCMV-DB sample was used as a positive control. NTC: no template control. lncRNA 4.9 (C) and lncRNA HOTAIR (D) transcript detection in the EZH2 IP samples of CEGBCs-DB and BL, as measured by RT-qPCR. Mouse anti-IgG was used as an isotype control. Data are represented as mean  $\pm$  SD of two independent experiments.

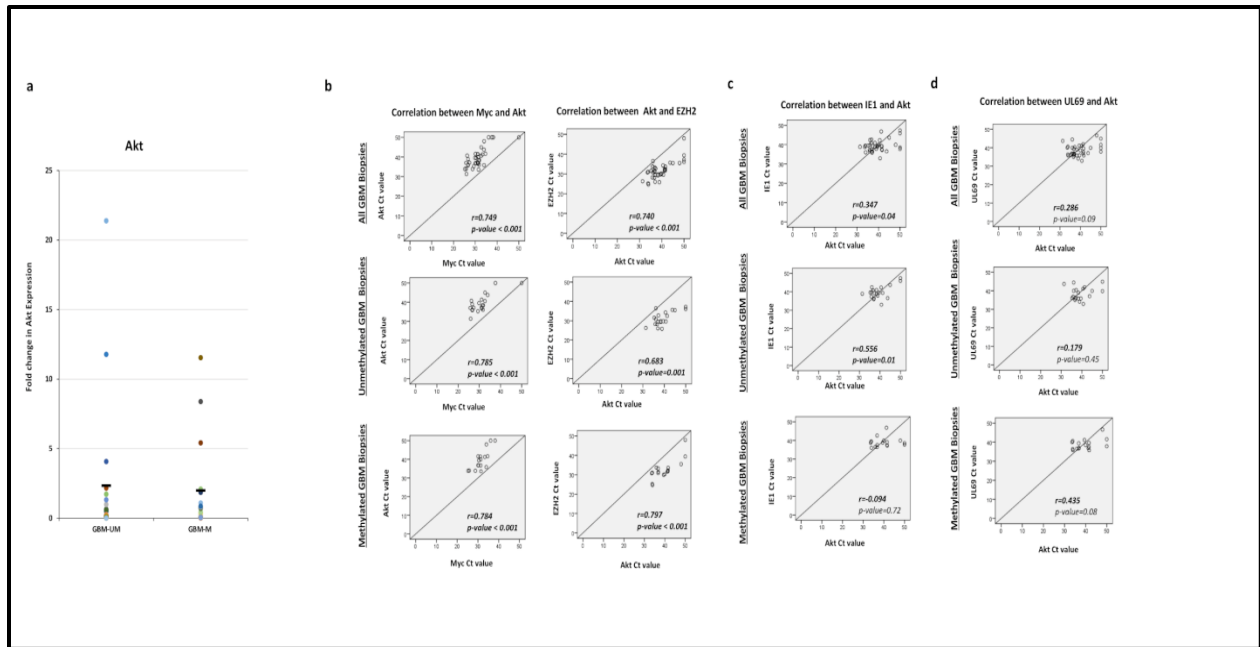

### 7.2.5 Upregulation of EZH2 and Myc in HCMV-positive GBM Tissues

To further decipher the role of HCMV and EZH2-Myc pathway in vivo, we analyzed 37 GBM biopsies (MGMT promoter methylated  $n = 17$  and MGMT promoter unmethylated  $n = 20$ ) for the presence of HCMV as well as EZH2 and Myc expression. Tumor biopsies displayed an enhanced EZH2 and Myc expression in both MGMT promoter methylated and unmethylated tissues, particularly in MGMT promoter unmethylated ones (**Figure 28B**). HCMV was detected in all GBM samples (100%) (**Table 7**). In all GBM biopsies, there was a statistically significant strong correlation between Myc and EZH2 expression (**Figure 28C**). A significant strong correlation was found between HCMV presence (IE1 gene) and Myc/EZH2 expression in unmethylated GBM biopsies ( $r = 0.690$ ,  $p$ -value = 0.001;  $r = 0.589$ ,  $p$ -value = 0.006; respectively) (**Figure 28D**). In unmethylated GBM biopsies, HCMV presence (UL69 gene) strongly correlated with Myc/EZH2 expression ( $r = 0.507$ ,  $p$ -value = 0.02 and  $r = 0.544$ ,  $p$ -value = 0.01, respectively) (**Figure 28E**). On the other hand, a weak to moderate correlation was detected between HCMV presence and Myc/EZH2 expression in methylated GBM biopsies (**Figure 28D,E**). Hence, we reported the detection of HCMV in GBM tumor biopsies displaying enhanced EZH2, Myc, and Akt expression (**Figure 28 and Figure 29**).

**Figure 28: HCMV detection as well as EZH2, and Myc expression in glioblastoma biopsies.**

(A) Glioblastoma multiforme tissue was stained using HES; magnification x40, scale bar 25  $\mu$ m. (B) Scattered plots showing Myc, and EZH2 expression in individual methylated, and unmethylated HCMV-positive GBM biopsies. Mean values are indicated. (C) Correlation test between Myc and EZH2 expression in all GBM biopsies, methylated, and unmethylated HCMV-positive GBM biopsies. Correlation test between IE1 (D) and UL69 (E) presence and the expression of Myc and EZH2. *p*-values were determined by Pearson's correlation test.

**Figure 29: Akt expression in glioblastoma biopsies.**

(A) Scattered plots showing Akt expression in individual methylated, and unmethylated HCMV-positive GBM biopsies. Mean values are indicated. (B) Correlation test between Myc and Akt expression, as well as EZH2 and Akt expression in all GBM biopsies, methylated, and unmethylated HCMV-positive GBM biopsies. Correlation test between IE1 (C) and UL69 (D) presence and Akt expression. p-values were determined by Pearson's correlation test.

### 7.2.6 Isolation of Oncogenic HCMV Strains From GBM Tumors

Among the thirty-seven GBM biopsies, eleven GBM biopsies were considered for HCMV isolation. Eleven HCMV-GBM strains were isolated from MGMT promoter methylated ( $n = 4$ ) and MGMT promoter unmethylated ( $n = 7$ ) GBM tumors by tissue disruption and filtration, and were subsequently grown in MRC5 cells showing a peak of viral load (1–3 log) around day 20 post-infection (**Figure 30A and Table 9**). Following HAs infection with the eleven HCMV-GBM strains, we detected cell clusters with irradiating low and high motility cells displaying a neural progenitor-like phenotype (**Figure 30B**) parallel to the sustained viral replication confirmed by FACS (**Figure 30C**) and IE1 gene detection by qPCR (**Figure 30D**). Viral transcripts (IE1 and UL69) were detected in HAs infected with methylated and unmethylated HCMV-GBM strains compared to uninfected HAs (**Figure 30E**). Upregulated Myc and EZH2 proteins and transcripts were detected in HAs infected with methylated and unmethylated HCMV-GBM strains, unlike

uninfected HAs (**Figure 30F,G,H and Table 9**). All HCMV-GBM isolates transformed HAs as measured by soft agar colony formation assay ( $p$ -value<sub>(UI HAs: HCMV-GBM)</sub> = 0.02;  $p$ -value<sub>(UI HAs: HCMV-GBM-M)</sub> = 0.04,  $p$ -value<sub>(UI HAs: HCMV-GBM-UM)</sub> = 0.03) (**Figure 30I**).

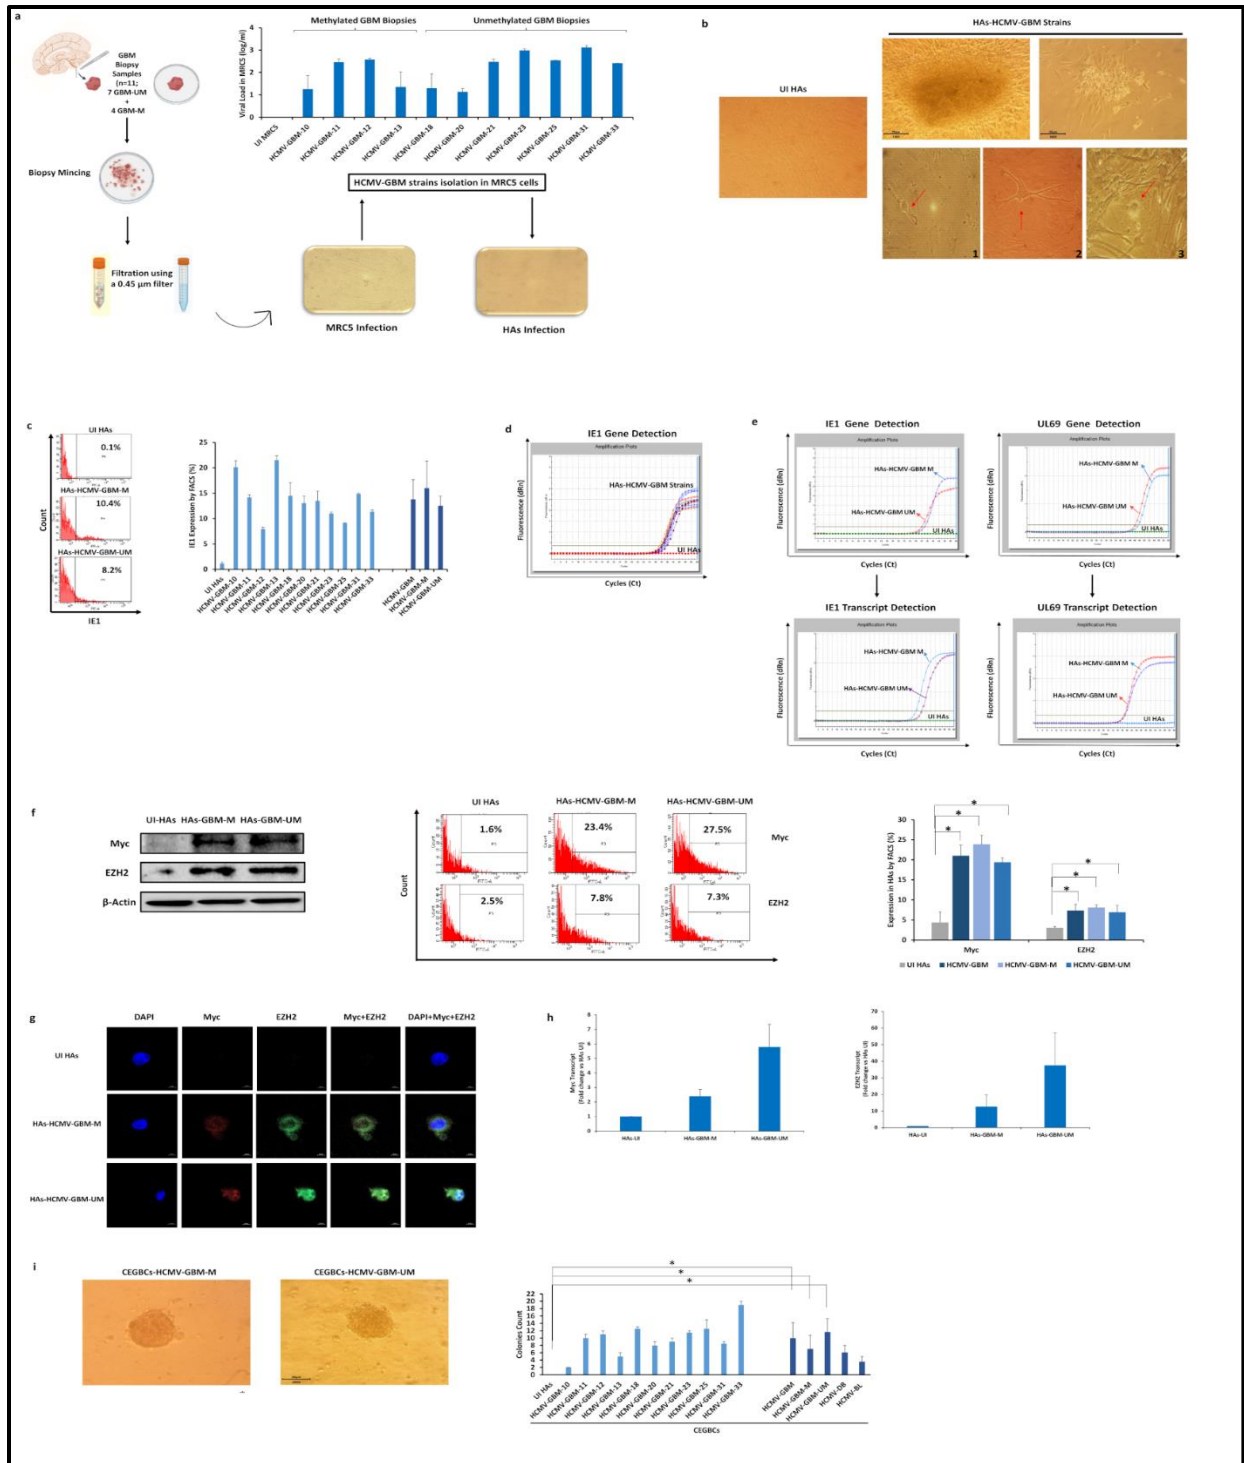

Figure 30: Isolation of oncogenic HCMV strains from GBM biopsies.

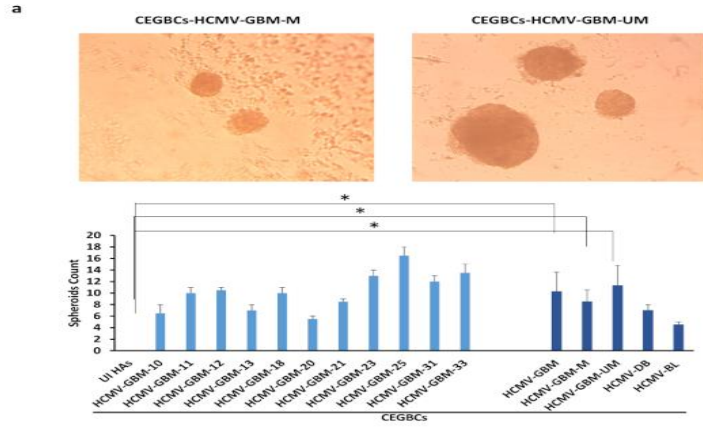

(A) Isolation protocol of eleven HCMV-GBM strains from GBM tissues; seven unmethylated and four methylated GBM biopsies. Histogram representing the viral replication of the isolated HCMV strains in MRC5 cultures. UI MRC5 cells were used as control. (B) The subsequent infection of HAs generating CEGBCs. Microscopic images showing the different cellular morphology (red arrows) generated in human astrocytes infected with the eleven isolated GBM HCMV strains; (1) neural progenitor cell (NPC)-like cells; (2) dendritic-like cells with cytoplasmic prolongation, and (3) PGCCs; magnification x100, scale bar 100  $\mu$ m. IE1 protein and gene expression in the isolated methylated and unmethylated promoter HCMV-GBM strains as measured by FACS (C) and qPCR (D), respectively; UI HAs were used as a control. (E) IE1 and UL69 gene and transcript detection in HAs infected with the isolated methylated and unmethylated promoter HCMV-GBM strains as measured by qPCR and RT-qPCR, respectively. (F) Myc and EZH2 expression in the isolated methylated and unmethylated GBM strains, as measured by western blot and FACS; uninfected HAs were used as a control.  $\beta$ -actin was used as loading control. Histogram representing Myc and EZH2 expression in uninfected HAs, the total isolated HCMV-GBM strains, methylated and unmethylated HCMV-GBM strains as measured by FACS. (G) Confocal microscopic images of Myc and EZH2 staining in HAs infected with the isolated methylated and unmethylated promoter HCMV-GBM strains. Nuclei were counterstained with DAPI; magnification  $\times 63$ , scale bar 10  $\mu$ m. (H) Myc and EZH2 transcripts detection by RT-qPCR. (I) Colony formation in soft agar seeded with CEGBCs generated from HAs infection with the isolated methylated and unmethylated promoter HCMV-GBM strains; UI HAs were used as a control. Formed colonies were observed under an inverted light microscope (Magnification 200x, scale bar 100  $\mu$ m). Histograms representing the number of colonies generated in all GBM strains as well as methylated and unmethylated HCMV-GBM strains. Data are represented as mean  $\pm$  SD of two independent experiments. \* $p$ -value  $\leq 0.05$ .

<b>Positive</b>	<b>[7/7]</b>	<b>[7/7]</b>	<b>[7/7]</b>	<b>[7/7]</b>	<b>[7/7]</b>	<b>[7/7]</b>
<b>TOTAL ISOLATED GBM BIOPSIES (n=11)</b>						
<b>Positive</b>	<b>[11/11]</b>	<b>[11/11]</b>	<b>[11/11]</b>	<b>[11/11]</b>	<b>[11/11]</b>	<b>[10/11]</b>

Spheroids were generated 24–48 hours post-seeding the HAs infected with the clinical HCMV-GBM strains ( $p$ -value<sub>(UI HAs: HCMV-GBM)</sub> = 0.02;  $p$ -value<sub>(UI HAs: HCMV-GBM-M)</sub> = 0.04,  $p$ -value<sub>(UI HAs: HCMV-GBM-UM)</sub> = 0.03) (**Figure 31A**). High SOX2 levels were detected in spheroids generated from the eleven HCMV-GBM strains (**Figure 31B and Table 9**). Nestin and IE1 were concomitantly expressed in spheroids generated from all HCMV-GBM strains (**Figure 31C**). Spheroids generated from the HCMV-GBM strains did not express GFAP unlike uninfected HAs. Further, a 3D collagen-invasion assay was performed to evaluate the invasiveness potential of the spheroids generated from HCMV-GBM strains (**Figure 31D**). The lncRNA4.9 gene was detected in CEGBCs derived from HCMV-GBM strains (**Figure 31E**). Viral lncRNA4.9 and cellular lncRNA HOTAIR transcripts were detected in the EZH2 immunoprecipitated samples corresponding to CEGBCs derived from all HCMV-GBM strains, mostly from MGMT promoter unmethylated HCMV-GBM strains, using RNA CLIP assay ( $p$ -value<sub>(UI HAs:GBM)</sub> = 0.03;  $p$ -value<sub>(UI HAs: GBM-M)</sub> = 0.07;  $p$ -value<sub>(UI HAs: GBM-UM)</sub> = 0.04) (**Figure 31F**).

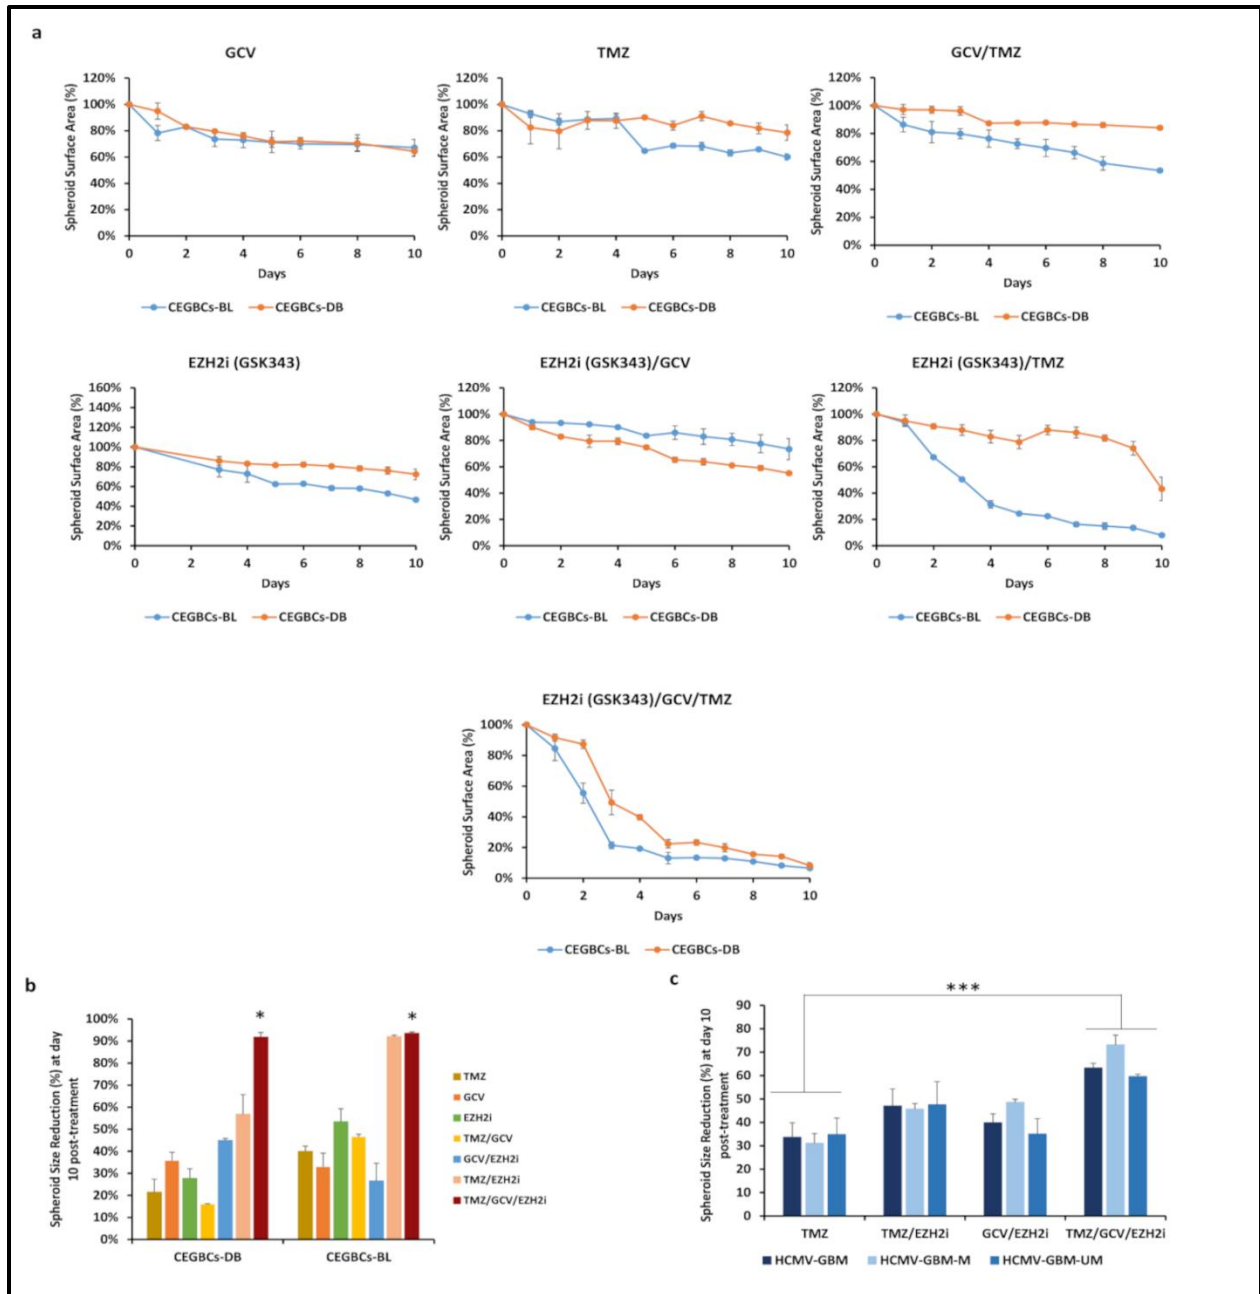

### **Figure 31: Spheroid forming and invasion potentials of the HCMV-GBM strains and the detection of lncRNA 4.9 and HOTAIR transcripts.**

(A) Microscopic images of the spheroids generated from the isolated GBM HCMV strains; magnification  $\times 100$ , scale bar 20  $\mu\text{m}$ . Histograms representing the number of spheroids generated in all HCMV GBM strains as well as methylated and unmethylated HCMV-GBM strains; UI HAs were used as a control. Confocal microscopic images of SOX2 (B) and concomitant Nestin/IE1 (C) staining in spheroids generated from the isolated HCMV-GBM strains. Nuclei were counterstained with DAPI; magnification  $\times 63$ , scale bar 10  $\mu\text{m}$ . (D) Microscopic images showing the invasion potential of CEGBCs through protrusions and cell migration (red arrows); magnification  $\times 200$ , scale bar 20  $\mu\text{m}$ . (E) lncRNA 4.9 gene detection in the supernatants of HAs infected with the isolated HCMV-GBM strains using qPCR; UI HAs were used as a control. (F) Interaction of lncRNA4.9 and HOTAIR transcripts with EZH2 in CEGBCs-GBM using RNA cross-linking immunoprecipitation (CLIP) assay.

#### 7.2.7 EZH2 inhibitor, TMZ, and GCV tritherapy Curtails CEGBCs Growth

Although TMZ is known as the first-choice chemotherapeutic agent in glioblastoma, TMZ resistance often becomes a limiting factor in effective glioblastoma treatment [373,374]. Herein, we evaluated EZH2 inhibitor GSK343, GCV and TMZ efficacy as single therapies, as well as bi- or tri-combination therapy on CEGBCs-DB, BL, and GBM spheroids (**Figure 32**). TMZ reduced spheroids' size by 23% only in CEGBCs-BL cultures, unlike CEGBCs-DB which displayed more mesenchymal traits ( $p\text{-value}_{(\text{CEGBCs-DB:CEGBCs-BL})} = 0.03$ ). GCV reduced the spheroids' size by 21% and 24% in CEGBCs-DB and BL, respectively ( $p\text{-value}_{(\text{CEGBCs-DB:CEGBCs-BL})} = 0.35$ ). On the other hand, GCV/TMZ combination therapy lead to a 27% size reduction of CEGBCs-BL spheroids, meanwhile having a very limited effect in CEGBCs-DB in which the spheroids' size was reduced by 9% ( $p\text{-value}_{(\text{CEGBCs-DB:CEGBCs-BL})} < 0.01$ ) (**Figure 32A**). Spheroids of CEGBCs-DB and BL were treated by GSK343, GSK343/GCV, GSK343/TMZ, and GSK343/GCV/TMZ. CEGBCs-DB were resistant to mostly all therapies except the triple therapy ( $p\text{-value}_{(\text{CEGBCs-DB:CEGBCs-BL})} = 0.06$ ) unlike CEGBCs-BL that were mainly responsive to GSK343/TMZ ( $p\text{-value}_{(\text{CEGBCs-DB:CEGBCs-BL})} < 0.001$ ) and triple treatment ( $p\text{-value}_{(\text{CEGBCs-DB:CEGBCs-BL})} = 0.06$ ) (**Figure 32A**). Under triple therapy (GSK343/GCV/TMZ), spheroids' size was reduced by around 90% in CEGBCs-DB and BL at day 10 post-treatment ( $p\text{-value}_{(\text{triple therapy: TMZ})} = 0.02$ ) (**Figure 32B**). Spheroids' size was reduced by around 60% with all the eleven HCMV-GBM strains at day 10 post-triple treatment (GSK343/GCV/TMZ) ( $p\text{-value}_{(\text{triple therapy: TMZ})} < 0.001$ ) (**Figure 32C**), similar to that reported for DB and BL strains.

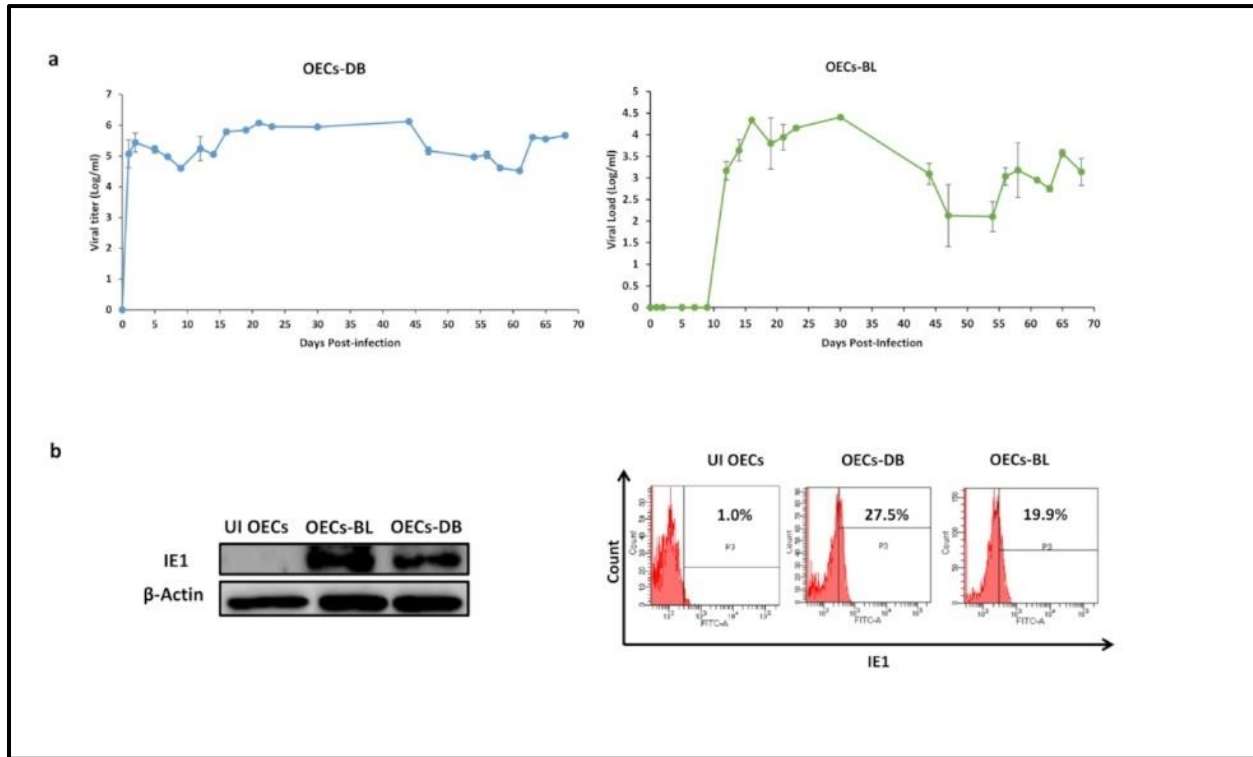

**Figure 32: The effect of diverse single and combination therapies on CEGBCs' growth.**

(A) Curves representing the spheroid surface area corresponding to CEGBCs-DB and BL under GCV(20  $\mu$ M), TMZ(50  $\mu$ M), GCV(20  $\mu$ M)/TMZ(50  $\mu$ M), GSK343 (0.1  $\mu$ M), GSK343 (0.1  $\mu$ M)/ GCV(20  $\mu$ M), GSK343 (0.1  $\mu$ M)/TMZ(50  $\mu$ M), and GSK343 (0.1  $\mu$ M)/GCV(20  $\mu$ M)/TMZ(50  $\mu$ M) therapies. (B) Histogram representing the CEGBCs-DB and BL spheroids size reduction 10 days post-treatment. Data are represented as mean  $\pm$  SD of two independent experiments. \* $p$ -value  $\leq$  0.05. (C) Histogram representing the CEGBCs-GBM spheroids size reduction at day 10 post-treatment. Data are represented as mean  $\pm$  SD of two independent experiments. \* $p$ -value  $\leq$  0.05; \*\*\* $p$ -value  $\leq$  0.001.

### 7.3 Polyploidy, EZH2 Upregulation, and Transformation in CMV-infected Human Ovarian Epithelial Cells

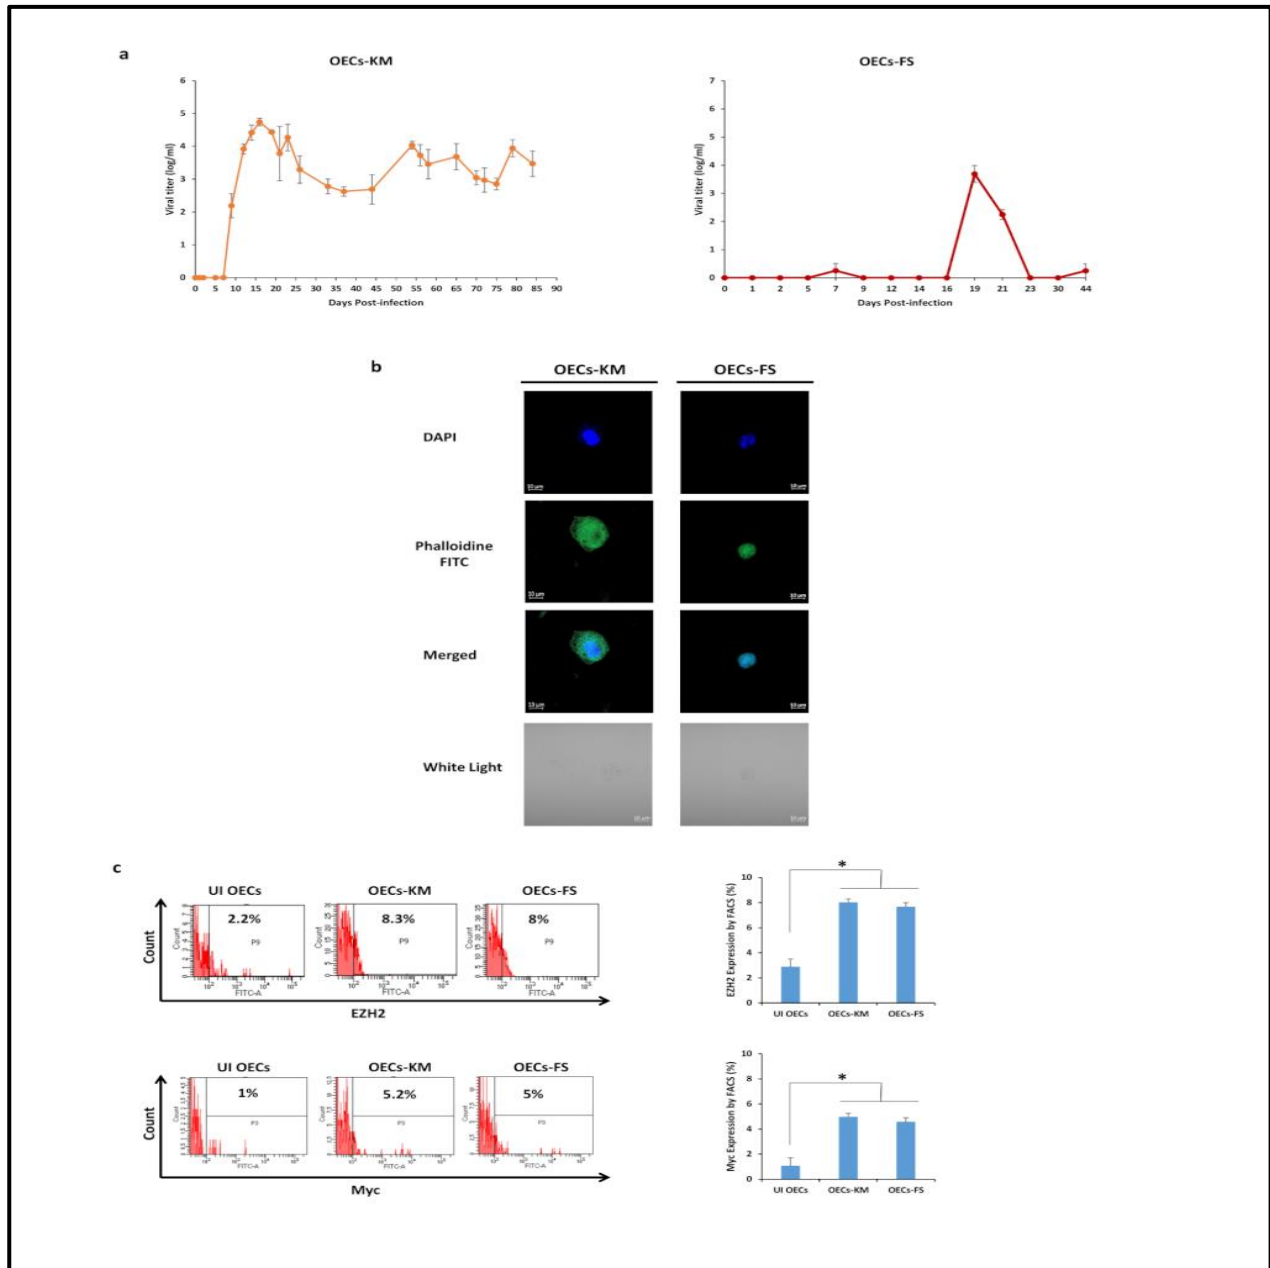

#### 7.3.1 OECs Chronically Infected With HCMV-DB and BL Strains Generated CTO Cells With PGCCs

Upon studying the tropism exhibited by HCMV in OECs, all HCMV clinical strains replicated showing a peak viral replication at day 21, 16, 16, and 19 post-infection in OECs infected with HCMV-DB, HCMV-BL, HCMV-KM, and HCMV-FS, respectively (**Figure 33A and Figure 34A**). The peak level of HCMV productive infection was 6 and 4 logs in OECs-DB and BL, respectively (**Figure 33A**). HCMV-IE1 and pp65 proteins were detected in OECs-DB and BL (**Figure 33B**).

**Figure 33: Replication of high-risk HCMV strains in OECs cultures.**

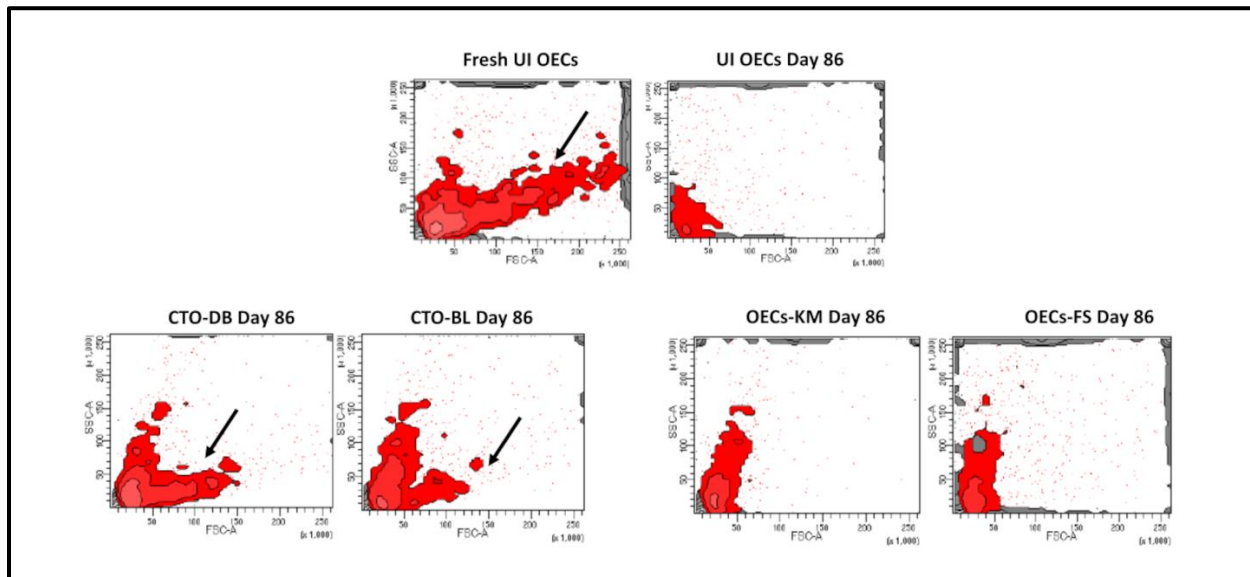

(A) Time-course of the viral titer in the supernatant of OECs infected with HCMV-DB and BL as measured by IE1-qPCR. (B) Immunoblotting data of IE1 in uninfected OECs lysates and OECs infected with HCMV-DB and BL (day 5 post-infection).  $\beta$ -actin was used as loading control. IE1 expression by FACS in acutely infected OECs-DB and BL; UI OECs were used as a control.

**Figure 34: Replication of low risk HCMV strains in OECs cultures.**

(A) Time-course of the viral titer in the supernatant of OECs infected with HCMV-KM and FS as measured by IE1-qPCR. (B) Confocal microscopic images of DAPI and phalloidine staining in OECs infected with HCMV-KM and FS. (C) FACS staining of EZH2 and Myc in uninfected OECs as well as OECs-KM and FS. Data are represented as mean  $\pm$  SD of two independent experiments. \* p-value  $\leq$  0.05.

We noticed the existence of large-sized cells having large nuclei that were detected only in OECs chronically infected with the high-risk HCMV-DB and BL strains compared to uninfected OECs (**Figure 36A**) and OECs chronically infected with HCMV-KM and FS strains (**Figure 34B**). Further, around three months post-infection, cellular survival was noted only in the chronically infected OECs-DB and BL compared to OECs-KM and FS (**Figure 35**). The emerging cells were termed “*CMV-Transformed Ovarian epithelial cells*” or CTO similar to the transformed cells that were previously reported by our group, namely, “*CMV-Transformed Human mammary epithelial cells*” or CTH cells and “*CMV-Elicited Glioblastoma Cells*” or CEGBCs [125,209,375].

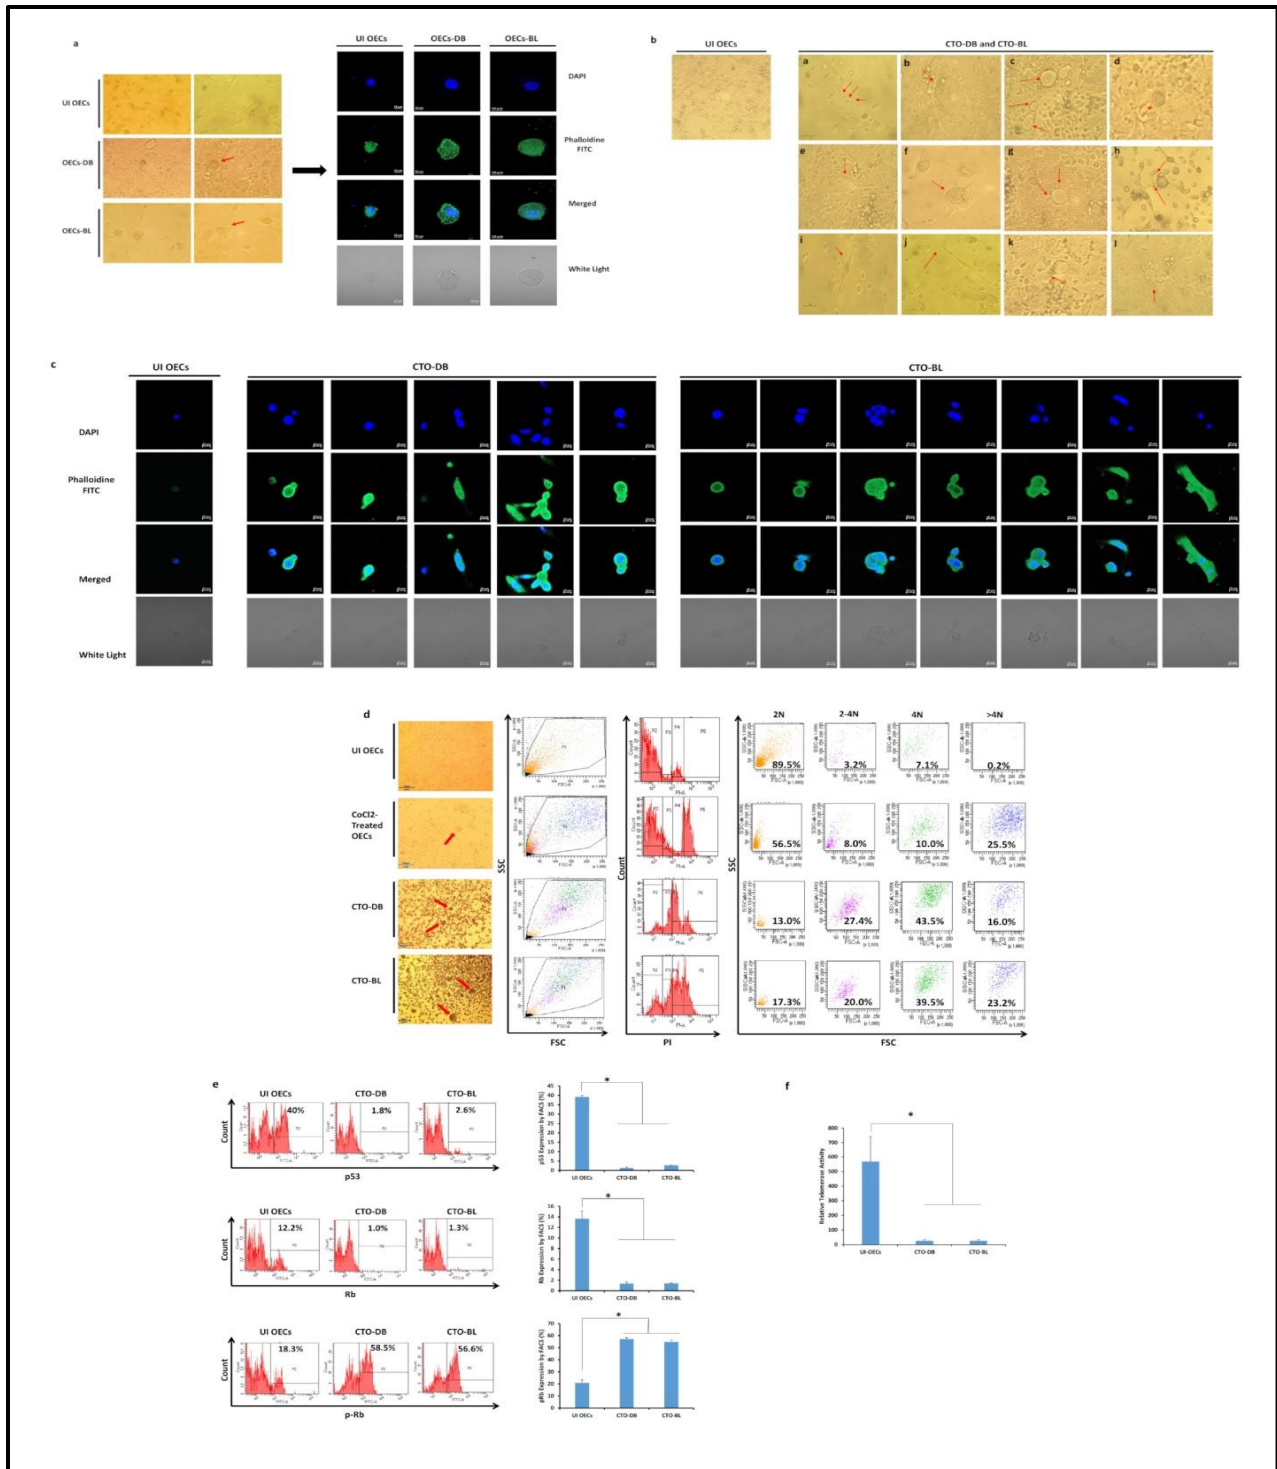

**Figure 35: Flow cytometric analysis based on FSC and SSC of uninfected OECs as well as chronically infected OECs.**

Only chronically-infected OECs-DB and BL, namely CTO-DB and CTO-BL cells, and not the chronically-infected OECs-KM and FS were alive at day 86 post-infection (black arrows).

After applying a morphology-based classification, cellular heterogeneity was detected in CTO-DB and BL cultures including giant cells, blastomeres, blastocytes, multinucleated, mesenchymal, budding, and lipid droplets-rich cells as well as cells exhibiting filopodia and cytoplasmic vacuolization (**Figure 36B**). Some of the aforementioned morphologies were further confirmed by confocal microscopy showing mainly multinucleated and mesenchymal cells, asymmetric division, budding, and cells with giant nuclei (**Figure 36C**). A high percentage of tetraploidization and polyploidy cells was detected in CTO-DB and BL compared to UI OECs (**Figure 36D**). CTO-

DB and BL populations were classified into PGCCs ( $\geq 4 N$ ), intermediate cells (ICs of 2–4 N), and small cells (SCs of 2 N) (**Figure 36D**). As a positive control, cobalt chloride ( $\text{CoCl}_2$ ) was used to induce PGCCs formation in OECs cultures (**Figure 36D**).

Since the blockade of tumor suppressors and decreased telomerase activity have been correlated with tetraploidization in several human cancers [376], p53 and Rb expression as well as telomerase activity were assessed in uninfected OECs, CTO-DB, and CTO-BL (**Figure 36E,F**). Downregulation of p53 and Rb proteins was noticed in CTO-DB and BL compared to controls ( $p$ -value  $_{(\text{UI OECs:CTO-HCMV})} = 0.03$ ), unlike pRb which was upregulated in CTO-DB and BL ( $p$ -value  $_{(\text{UI OECs:CTO-HCMV})} = 0.03$ ) (**Figure 36E**). Notably, telomerase activity was relatively low or undetectable in CTO-DB and BL compared to uninfected OECs ( $p$ -value = 0.03) (**Figure 36F**). Hence, p53 and Rb downregulation along with decreased telomerase activity are sufficient to drive polyploidization in CTO-DB and BL, as previously reported [376].

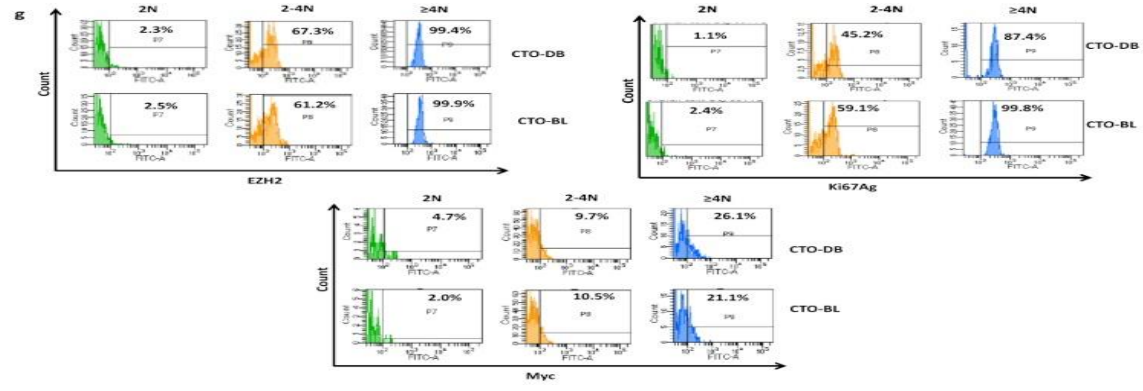

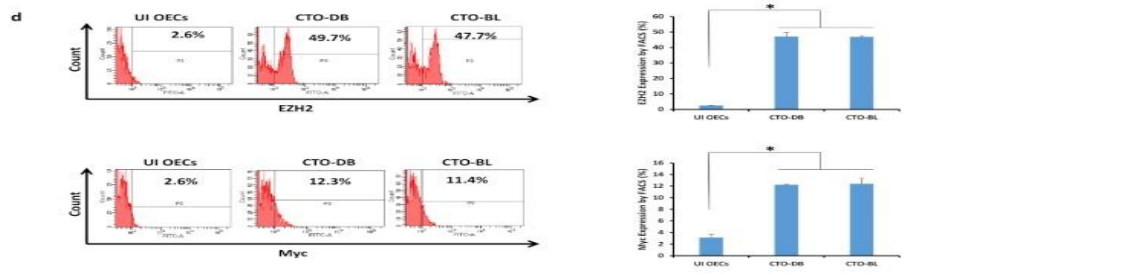

**Figure 36: Chronic infection of OECs with the high-risk HCMV clinical isolates and polyploidy detection in OECs cultures.**

(A) Microscopic images including confocal images of DAPI and phalloidine staining in OECs infected with HCMV-DB and BL; uninfected OECs were used as a negative control. Left panel: magnification  $\times 100$  and  $\times 200$ , scale bar 100 and 50  $\mu\text{m}$ ; Right panel: magnification  $\times 63$ , scale bar 10  $\mu\text{m}$ . Red arrows showing the PGCCs detected in OECs cultures. (B) The appearance of distinct cellular morphologies of the giant cell cycle including (a) filopodia, (b, c, d) blastomeres and blastocytes, (e) lipid droplets-filled cells, (f) multinucleated, (g, h) budding, (i) mesenchymal cells as well as (j, k, l) few atypical morphologies; magnification  $\times 100$ , scale bar 100  $\mu\text{m}$ . Uninfected OECs were used as a control. (C) Confocal microscopic images of DAPI and phalloidine staining in CTO-DB and BL. Uninfected OECs were used as a negative control; magnification  $\times 63$ , scale bar 10  $\mu\text{m}$ . (D) Propidium iodide (PI) staining for polyploidy detection in HCMV-transformed OECs. Cobalt chloride ( $\text{CoCl}_2$ )-treated OECs (450  $\mu\text{M}$ ) were used as a positive control. Microscopic images of uninfected OECs as well as the PGCCs generated in CTO-DB and BL cultures and post-  $\text{CoCl}_2$  treatment; magnification  $\times 100$ , scale bar 100  $\mu\text{m}$ . (E) p53, Rb, and p-Rb expression in uninfected OECs and CTO-DB and BL by FACS. (F) Histograms representing the relative telomerase activity in uninfected OECs as well as CTO-DB and BL. Data are represented as mean  $\pm$  SD of two independent experiments. \* $p$ -value  $\leq 0.05$ .

### 7.3.2 CTO cells Display Dedifferentiation, Stemness, and EMT Characteristics

CTO-DB and BL were seeded in soft agar to assess their oncogenic transforming potential. Colony formation was detected in the cultures seeded with CTO-DB and BL, compared to uninfected OECs (**Figure 37A**). On the proteomic level, EZH2 and Myc upregulation was detected in CTO-DB and BL compared to uninfected OECs ( $p$ -value<sub>(UI OECs:CTO-HCMV)</sub> = 0.03) (**Figure 37B,C, and D**); on the contrary, a limited EZH2 and Myc upregulation was observed in OECs-KM and FS ( $p$ -value<sub>(UI OECs:OECs-HCMV)</sub> = 0.02) (**Figure 34C**). A significant positive correlation between EZH2 and Myc protein expression was detected in CTO cells ( $r = 0.983$ ,  $p$ -value  $< 0.001$ ) (**Figure 38**). Further, EZH2 and Myc transcripts were upregulated in CTO-DB and BL compared to uninfected controls ( $p$ -value<sub>(UI OECs:CTO-HCMV)</sub> = 0.03) (**Figure 37E**). Altogether, a remarkable EZH2 upregulation parallel to the limited increase in Myc expression was noticed in CTO infected with the high-risk HCMV-DB and BL strains. EZH2 and Myc were expressed mainly in the PGCCs subpopulation of CTO-DB and BL (**Figure 37G**). A limited increase in SUZ12 expression was observed in CTO-DB and BL compared to uninfected OECs ( $p$ -value<sub>(UI OECs:CTO-HCMV)</sub> = 0.03) (**Figure 39A,B**). Upon assessing the proliferative potential of OECs chronically infected with HCMV high-risk strains, Ki67Ag was highly prominent in CTO-DB and BL compared to uninfected OECs ( $p$ -value<sub>(UI OECs:CTO-HCMV)</sub> = 0.03) (**Figure 37F**). High Ki67Ag expression was detected in the large cells (**Figure 37G**).

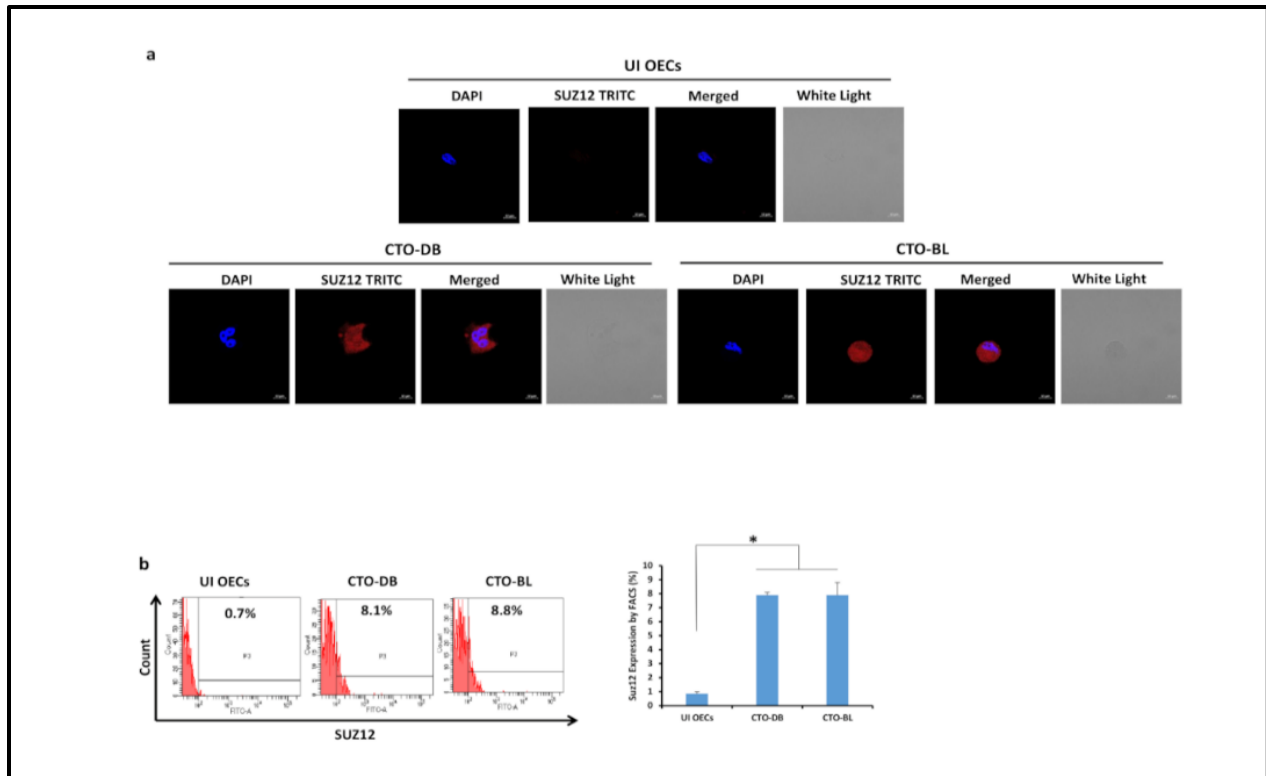

**Figure 37: Colony formation in soft agar and the phenotypic characterization of HCMV-transformed OECs.**

(A) Colony formation in soft agar seeded with CTO-DB and BL (MOI = 1); UI OECs were used as a negative control. Formed colonies were observed under an inverted light microscope (Magnification  $\times 200$ , scale bar  $50 \mu\text{m}$ ). Histogram representing the colony quantification/10,000 cells over days. (B) Immunoblotting data of EZH2 and Myc in uninfected OECs lysates and CTO-DB and BL.  $\beta$ -actin was used as loading control. (C) Confocal microscopic images of EZH2, Myc, and DAPI staining in CTO-DB and BL. UI OECs were used as controls; magnification  $\times 63$ , scale bar  $10 \mu\text{m}$ . (D) FACS staining of EZH2 and Myc in uninfected OECs as well as CTO-DB and BL. (E) EZH2 and Myc transcripts detection by RT-qPCR. (F) FACS staining of Ki67Ag in uninfected OECs as well as CTO-DB and BL. (G) EZH2, Myc, and Ki67Ag expression in CTO-DB and BL subpopulations (2 N, 2–4 N, and  $\geq 4$  N). Data are represented as mean  $\pm$  SD of two independent experiments. \* $p$ -value  $\leq 0.05$ .

**Figure 38: The assessment of the correlation between EZH2 and Myc expression in CTO cells.**

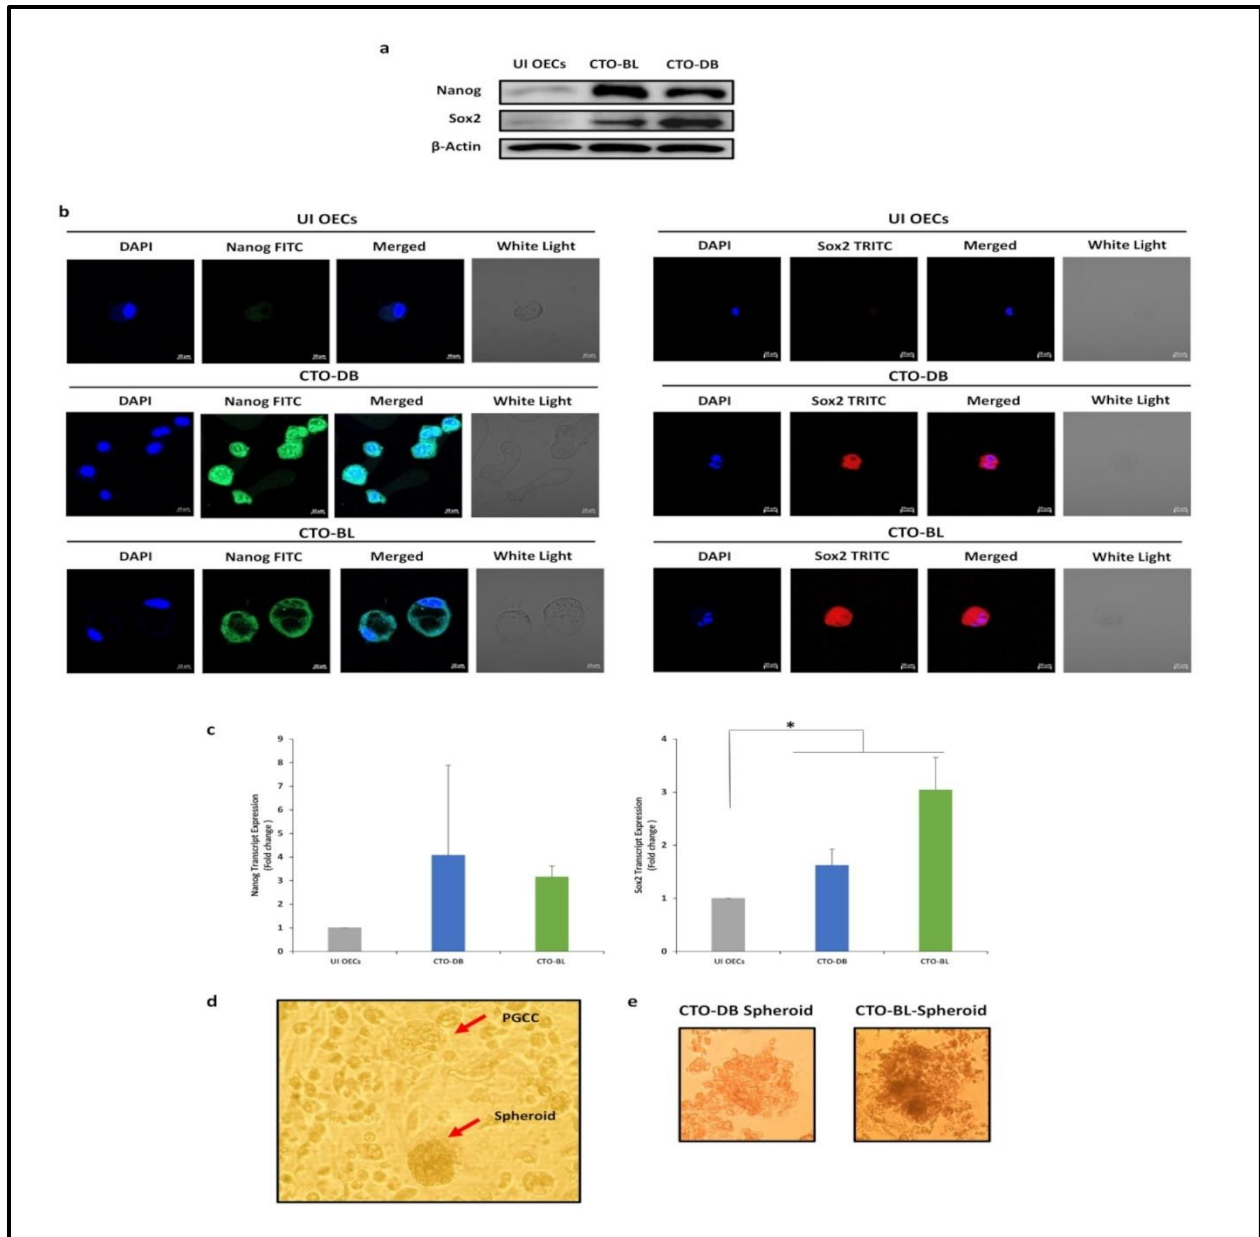

A significant-positive correlation detected between EZH2 and Myc protein expression in CTO-DB and BL cells.  $p$ -values were determined by Pearson's test.

**Figure 39: Expression of SUZ12 in CTO-DB and BL cells.**

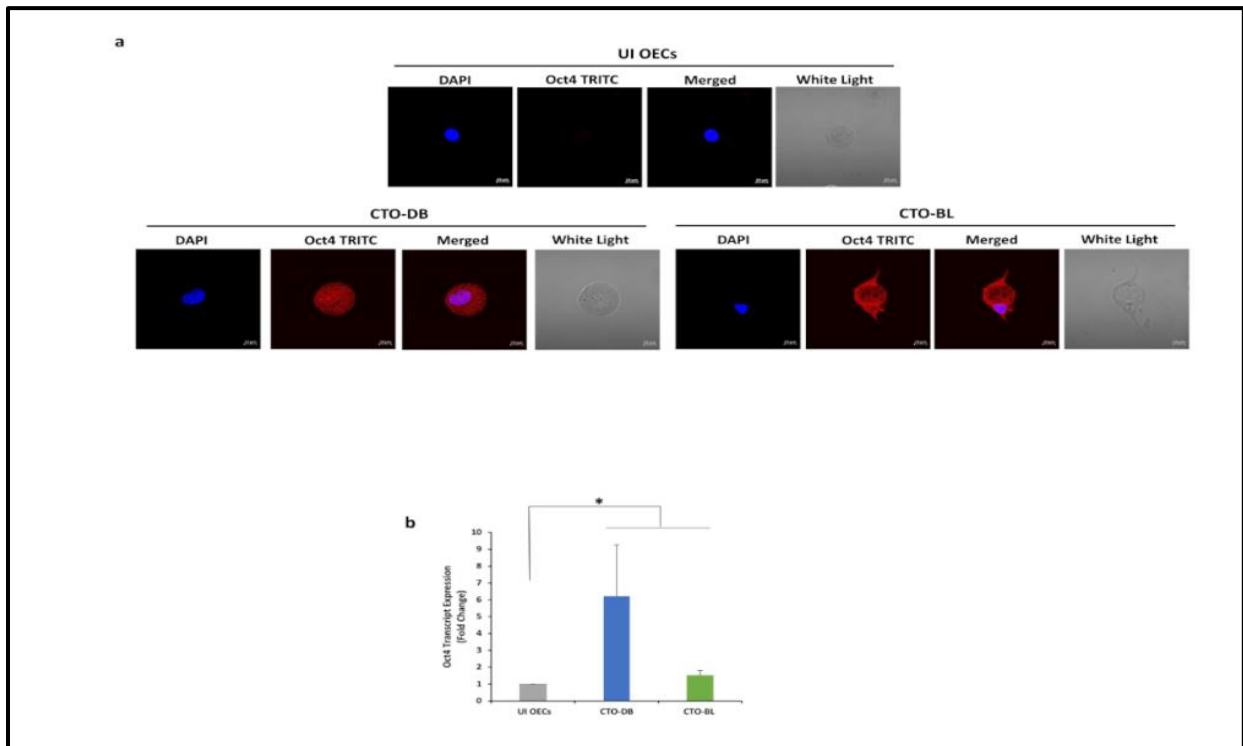

SUZ12 expression by (A) confocal microscopy and (B) FACS in CTO-DB and BL; uninfected OECs were used as a control. Nuclei were counterstained with DAPI; magnification  $\times 63$ , scale bar 10  $\mu\text{m}$ . Data are represented as mean  $\pm$  SD of two independent experiments. \*  $p\text{-value} \leq 0.05$ .

CTO-DB and BL displayed an embryonic stemness phenotype. The key regulatory genes maintaining the pluripotency and self-renewal properties of embryonic stem cells, Nanog, Sox2, and Oct4 were shown to be highly expressed in CTO-DB and BL compared to uninfected OECs (**Figure 40A,B, and Figure 41A**). Additionally, transcripts of Nanog, Sox2, and Oct4 were elevated in CTO-DB and BL (Nanog,  $p\text{-value}_{(\text{UI OECs:CTO-HCMV})} = 0.06$ ; Sox2 and Oct4,  $p\text{-value}_{(\text{UI OECs:CTO-HCMV})} = 0.03$ ) (**Figure 40C, and Figure 41B**). Besides PGCCs appearance in CTO-DB and BL cultures, it's worth mentioning the appearance of spontaneous spheroids in CTO-BL cultures (**Figure 40D**). Further, in the presence of methylcellulose, spheroids were generated in CTO-DB and BL cultures (**Figure 40E**). Finally, CD44, a marker of stemness and invasiveness, was upregulated in CTO-DB and BL cultures compared to uninfected OECs (**Figure 42**).

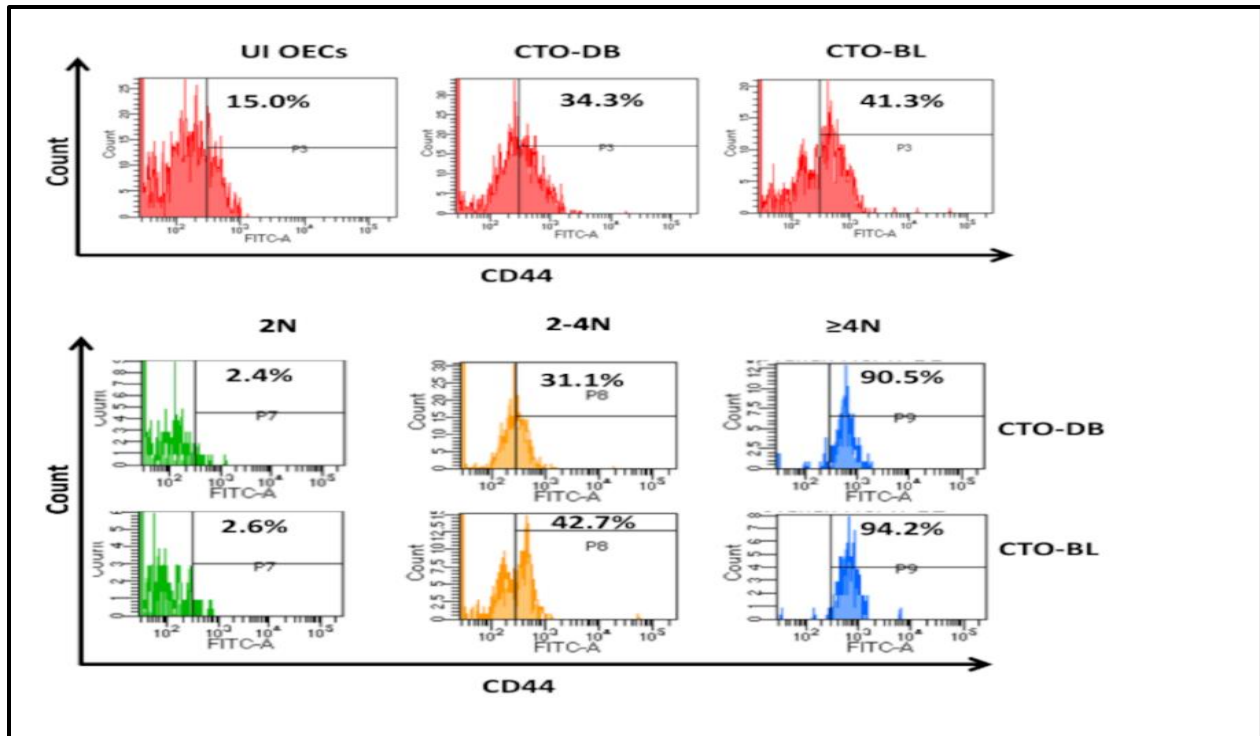

**Figure 40: HCMV-transformed OECs display an embryonic stemness phenotype and possess spheroid-forming potential.**

(A) Immunoblotting data of Nanog and Sox2 in uninfected OECs lysates and CTO-DB and BL.  $\beta$ -actin was used as loading control. (C) Nanog and Sox2 transcripts detection by RT-qPCR. Data are represented as mean  $\pm$  SD of two independent experiments. (D) Spontaneous spheroid formation and PGCCs were detected under an inverted light microscope in HCMV-transformed OECs cultures. Magnification  $\times 100$ , scale bar  $100 \mu\text{m}$ . (E) Spheroid generation from the chronically infected DB and BL OECs in methyl-cellulose assay; magnification  $\times 100$ , scale bar  $100 \mu\text{m}$ . \* $p$ -value  $\leq 0.05$ .

**Figure 41: Expression of Oct4 in CTO-DB and BL cells.**

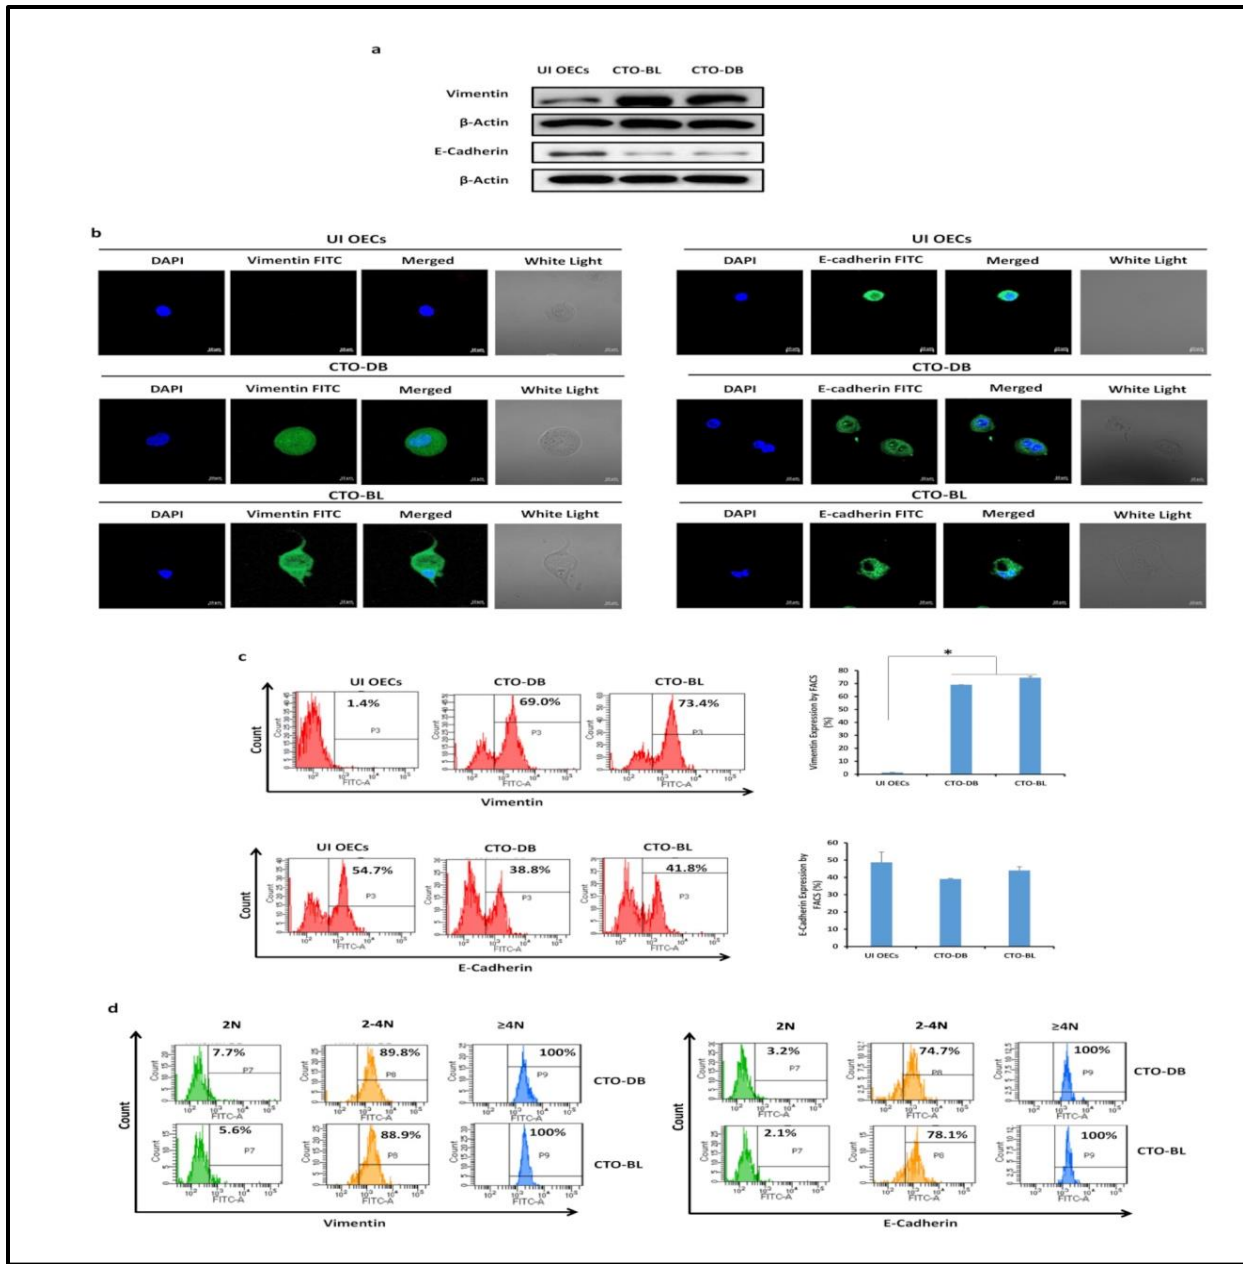

(A) Confocal microscopic images of Oct4 and DAPI staining in CTO-DB and BL cells. UI OECs were used as controls; magnification  $\times 63$ , scale bar 10  $\mu\text{m}$ . (B) Oct4 transcript detection by RT-qPCR. Data are represented as mean  $\pm$  SD of two independent experiments. \*  $p\text{-value} \leq 0.05$ .

**Figure 42: Expression of CD44 in CTO-DB and BL cells.**

FACS staining of CD44 in CTO-DB and BL whole and subpopulations; uninfected OECs were used as a control.

EMT fuels cancer progression, tumor cell invasion, and therapy resistance [377]. PGCCs gain strong invasiveness and migration ability after they undergo EMT [378]. Vimentin was strongly upregulated in DB and BL-infected OECs ( $p$ -value<sub>(UI OECs:CTO-HCMV)} = 0.03), whereas a slight decrease in E-cadherin was noticed compared to uninfected OECs ( $p$ -value<sub>(UI OECs:CTO-HCMV)} = 0.06) (Figure 43A,B, and C). Vimentin and E-cadherin were expressed mainly in the PGCCs and ICs subpopulations of CTO-DB and BL (Figure 43D). Altogether, the co-existence of vimentin and E-cadherin was detected in CTO-DB and BL, indicating a mesenchymal/epithelial hybrid state that was also accompanied with occasionally existing small cells possessing an elevated E-cadherin expression (Figure 43 and Figure 44). The co-existence of mesenchymal and epithelial phenotypes confirms the cellular plasticity of CTO-DB and BL. As a control, EZH2, Myc, Ki67Ag, Vimentin, E-cadherin, and CD44 protein expression in the subpopulations of uninfected OECs was provided in Figure 45.</sub></sub>

**Figure 43: HCMV infection of OECs enhances EMT/MET hybrid traits.**

### 7.3.3 Lytic and Latent HCMV Replication in Transformed OECs

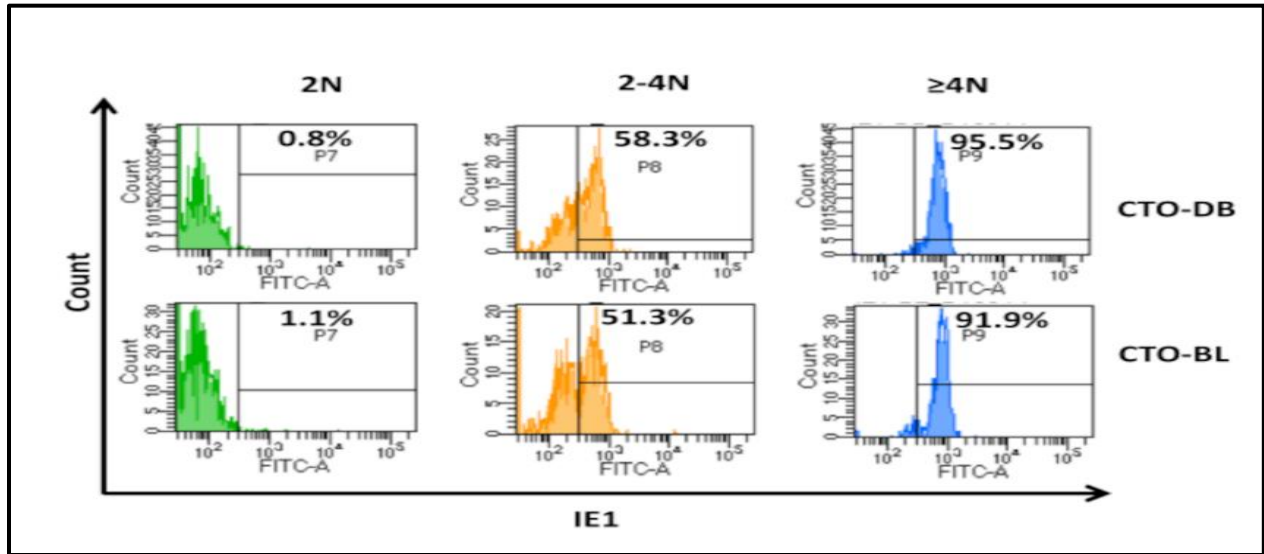

Sustained HCMV replication was confirmed in OECs chronically infected with HCMV-DB and BL, namely CTO-DB and BL (**Figure 46**). IE1 protein was remarkably detected in CTO-DB and BL versus uninfected OECs (**Figure 46A,B**); elevated IE1 expression was detected mainly in the PGCCs subpopulation compared to ICs and SCs (**Figure 47**). IE1 and UL69 genes and transcripts were detected in CTO-DB and BL compared to uninfected OECs (**Figure 46C,D**), indicating lytic HCMV replication. In addition, HCMV latency in CTO-DB and BL cultures was established by IE1 reactivation that was observed post-TPA treatment ( $p$ -value<sub>(CTO:TPA treated CTO)</sub> = 0.02) (**Figure 46E and Figure 48**).

Given that EZH2 is considered a major tumor marker and an effective therapeutic target for OC, herein, we evaluated the impact of two EZH2 inhibitors (GSK343 and EPZ6438) on CTO proliferation and polyploidization. Upon EZH2 blockade (**Figure 49**), detection of HCMV-IE1 gene was suppressed (**Figure 46F**). Ki67Ag protein expression was decreased post-EZH2 inhibitor treatment of CTO-DB and BL compared to untreated CTO cells ( $p$ -value<sub>(CTO:EZH2 inhibitors treated CTO)</sub> = 0.004) (**Figure 46G**). Upon assessing the PI expression in the subpopulations of CTO cells, GSK343 and EPZ6438 reduced tetraploidization and polyploidization in treated CTO cells compared to controls ( $p$ -value<sub>(CTO:EZH2 inhibitors treated CTO)</sub> = 0.007 and 0.004, respectively) (**Figure 46H**).

**Figure 46: Sustained HCMV replication in chronically HCMV-infected OECs.**

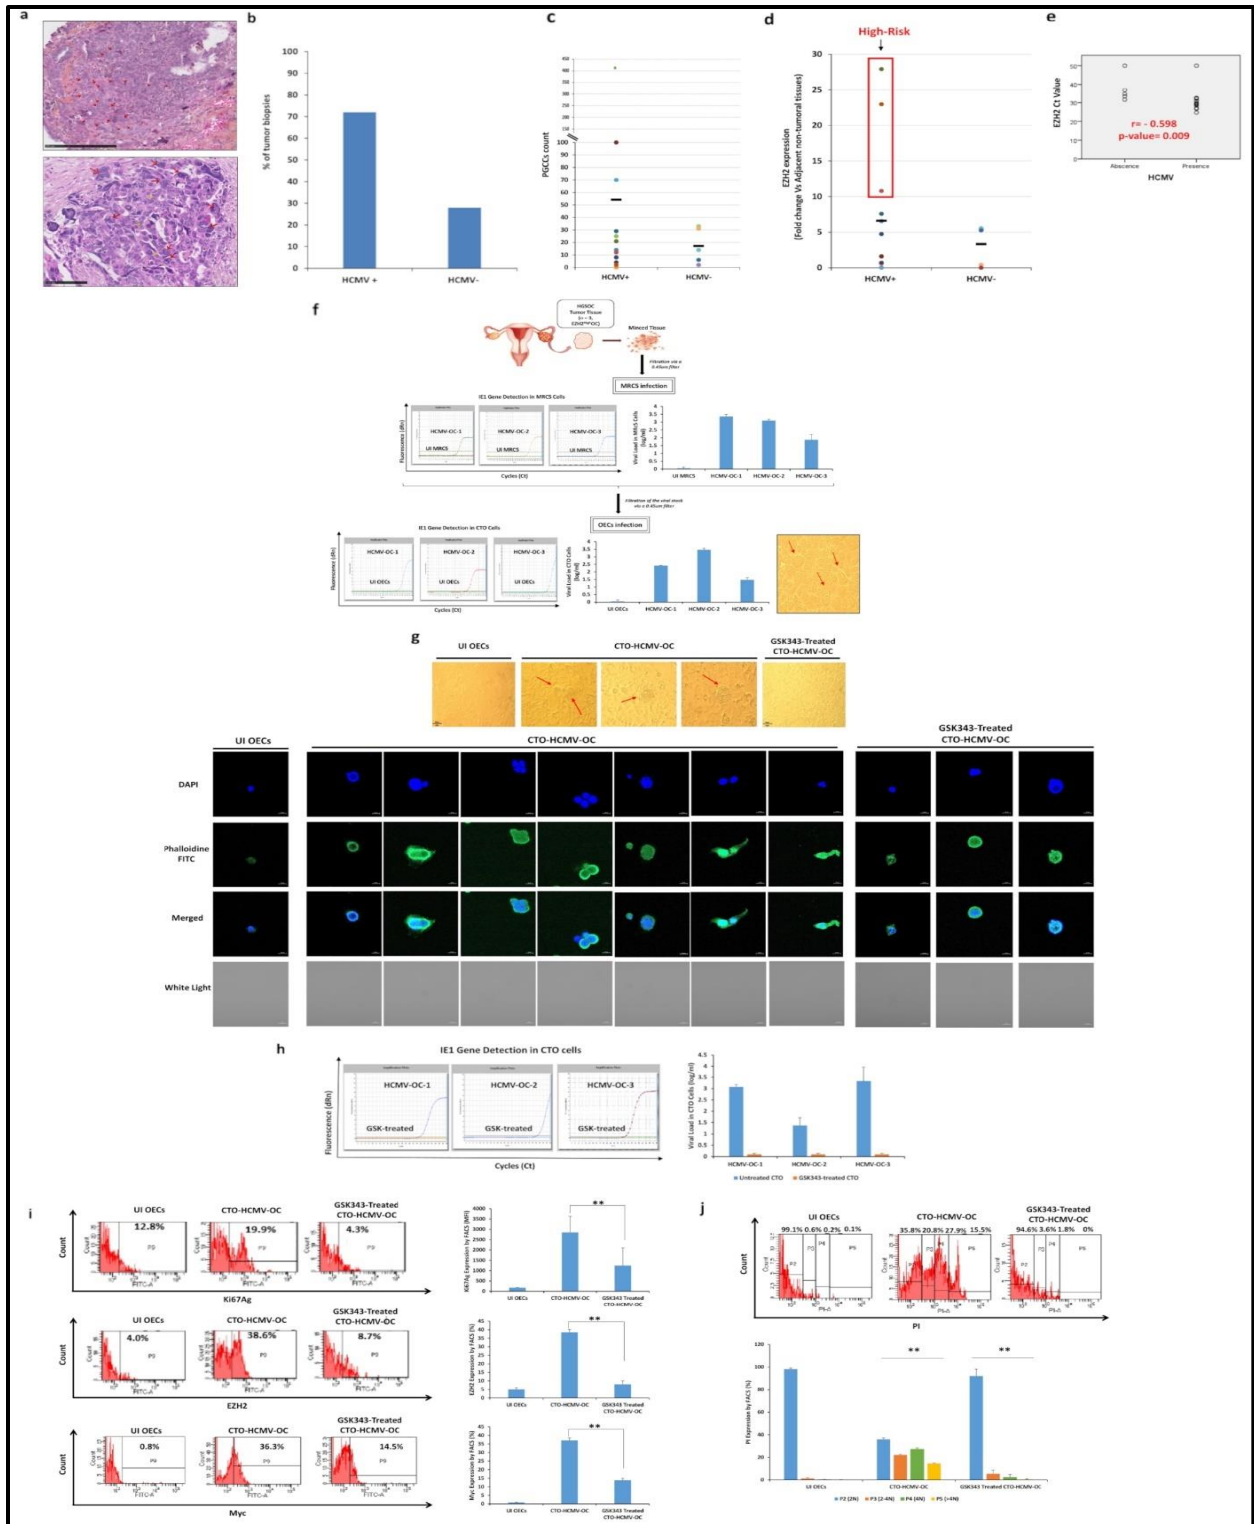

**Figure 49: EZH2 expression in untreated CTO-DB/BL and CTO-DB/BL treated with 0.1  $\mu$ M of GSK343 and EPZ6438 by FACS.**

#### 7.3.4 EZH2 Upregulation in HCMV-positive HGSOC Biopsies and The Isolation of Three Oncogenic HCMV Strains From EZH2<sup>High</sup> HGSOC Biopsies

To further assess the role of HCMV, EZH2, and PGCCs induction in vivo, we analyzed 25 OC biopsies (HGSOC biopsies  $n = 18$  and adjacent non-tumoral biopsies  $n = 7$ ) (**Table 8**) for the presence of HCMV, PGCCs count, as well as EZH2, Myc, and Akt expression (**Figure 50, Figure 51, and Figure 52**). PGCCs with giant or multiple nuclei were detected in the HGSOC biopsies (**Figure 50A**). HCMV was detected in 72% of HGSOC biopsies (**Figure 50B**). Elevated PGCCs count was mainly detected in HCMV-positive HGSOC biopsies (**Figure 50C**). HCMV-positive tumor biopsies displayed mostly an enhanced EZH2 and Akt with a limited Myc expression (**Figure 50D, Figure 51, and Figure 52A**). A significant positive correlation was found between HCMV presence and EZH2 as well as Akt expression ( $r = -0.598$ ,  $p$ -value = 0.009 and  $r = -0.466$ ,  $p$ -value = 0.05, respectively, based on Ct values) (**Figure 50E, and Figure 52B**). A significant positive correlation was detected between Akt expression and EZH2 as well as Myc expression ( $r = 0.420$ ,  $p$ -value = 0.015 and  $r = 0.620$ ,  $p$ -value = 0.006, respectively) (**Figure 52B**).

Among the eighteen HCMV-positive HGSOC biopsies, three biopsies with the highest EZH2 expression were considered for HCMV isolation. The three HCMV-OC strains were isolated by tissue disruption and filtration, and were subsequently grown in MRC5 cells showing a peak of viral load of 3 logs around day 7 post-infection (**Figure 50F**). Following OECs infection with the three HCMV-OC strains, HCMV presence was confirmed by the detection of IE1 gene in addition to the morphological changes that appeared in the OECs infected cultures, for instance, giant and multinucleated cells showing cell budding as well as mesenchymal cells (**Figure 50F,G**). Post-EZH2 inhibition, using GSK343, no HCMV replication was detected in addition to the absence of morphological heterogeneity in the infected cultures (**Figure 50G,H**). Upregulation of Ki67Ag, EZH2, and Myc expression was observed in CTO-HCMV-OC compared to uninfected OECs and GSK-treated CTO-HCMV-OC cells (Ki67Ag  $p$ -value (CTO:GSK343-CTO) = 0.01; EZH2  $p$ -value (CTO:GSK343-CTO) = 0.002; Myc  $p$ -value (CTO:GSK343-CTO) = 0.002). GSK343 reduced Ki67Ag, EZH2, and Myc expression by 56%, 79%, and 63%, respectively (**Figure 50I**). EZH2 inhibition reduced PGCCs percentage in infected cultures compared to untreated CTO cells ( $p$ -value = 0.002) (**Figure 50J**).

**Figure 50: HCMV detection, PGCCs presence as well as EZH2 expression in ovarian cancer biopsies.**

(A) Ovarian cancer tissue HES staining; magnification  $\times 400$ , scale bar  $250\ \mu\text{m}$  (upper panel) and  $100\ \mu\text{m}$  (lower panel). Red arrow representing the PGCCs while the yellow arrow represents the diploid carcinoma cells. (B) Histogram representing HCMV presence in the ovarian tumor biopsies. (C) Scattered plots showing the PGCCs count in HCMV-positive and negative ovarian tumor biopsies. (D) Scattered plots representing EZH2 expression in HCMV-positive and negative ovarian tumor biopsies by RT-qPCR. Red box indicates the high-risk HCMV strains with high EZH2 expression. (E) Correlation test between Ct value of EZH2 and HCMV presence  $p$ -values were determined by Spearman's correlation test. (F) Isolation protocol of the three high-risk HCMV-ovarian cancer strains from HGSOc tissues; histogram representing the viral replication of the isolated HCMV strains in MRC5 cells and CTO cultures by IE-qPCR. CTO cells were observed under an inverted light microscope (magnification  $\times 200$ , scale bar  $50\ \mu\text{m}$ ). (G) Light microscopic images (magnification  $\times 200$ , scale bar  $50\ \mu\text{m}$ ) as well as confocal images of DAPI and phalloidine staining in CTO-HCMV-OC and GSK343-treated CTO cells (magnification  $\times 63$ , scale bar  $10\ \mu\text{m}$ ); uninfected OECs were used as a negative control. (H) IE1 gene detection in CTO-HCMV-OC and GSK343-treated CTO cells by IE-qPCR. Ki67Ag, EZH2, Myc expression (I) and PI staining (J) in CTO-HCMV-OC, GSK343-treated CTO cells, and uninfected OECs by FACS. Data are represented as mean  $\pm$  SD of two independent experiments. \*\* $p$ -value  $\leq 0.01$ .

Scattered plot representing Myc expression in HCMV-positive and negative ovarian tumor biopsies by RT-qPCR.

**Figure 52: Akt Expression in ovarian cancer biopsies.**

(A) Scattered plot representing Akt expression in HCMV-positive and negative ovarian tumor biopsies by RT-qPCR. (B) A correlation detected between Akt expression (Ct value) and HCMV presence, in addition to Akt expression and EZH2 as well as Myc expression. p-values were determined by Spearman, Kendall's Tau, and Pearson correlation tests, respectively.

## Chapter 8

### 8. Discussion

Understanding the potential connections between viral infections and oncogenesis has been an ongoing area of research. In the context of breast cancer and to the best of our knowledge, our study demonstrated the oncogenic transformation and stemness potential of HCMV-B544 and B693 strains that were isolated from TNBC biopsies and indicated a differential treatment response depending on the HCMV strain present in the tumor. CTH-B544 and CTH-B693 cells are heterogeneous cellular populations that give rise to PGCCs, and display dedifferentiating phenotypes with stemness features as well as hybrid epithelial/mesenchymal phenotypes, resembling the morphological features found in aggressive cancers.

Myc activation has been widely described in breast cancer progression and can be used as a predictive marker for cancer staging, therapy resistance, and prognosis [331]. It is noteworthy that both B544 and B693 HCMV strains were isolated from  $EZH2^{High}Myc^{High}$ -expressing TNBC [126], further indicating a potential link between the presence of these HCMV strains and cancer progression. The coupling of c-Myc overexpression with Akt pathway activation observed in CTH cells is in line with previous findings [125]. Moreover, colony formation was detected in CTH-B544 and CTH-B693 cells associated with a high expression level of Ki67 Ag and c-Myc overexpression, thus revealing cellular transformation and their oncogenic potential which is consistent with the previously reported CTH data [125]. Ki67, a prognostic biomarker in invasive breast cancer, is not only required for cell proliferation in tumors but is also strongly linked to tumor initiation, growth, and metastasis [379]. PGCCs formation was promoted in hypoxic environments. It is worth noting that hypoxia inducible factor 1 alpha (HIF-1 $\alpha$ ) expression is induced by HCMV infection [210]. In PGCCs, the evaluation of metabolic reprogramming revealed the presence of PLIN4, a perilipin covering the lipid droplets especially in chemo-resistant tumors [118]; the Warburg effect [380] and the involvement of the glycolytic pathway were also found to be induced in cancer environments and upon HCMV infection [117]. PGCC-bearing CTH cells acquired embryonic-like stemness and an epithelial-mesenchymal hybrid phenotype. Studies have shown that the acquisition of the EMT and stemness properties lead to an

increase in the invasiveness and the metastatic potential of cancer cells within tumors [367]. The embryonic stem cells transcriptional network is based on the presence of master pluripotency regulators, Oct4, SSEA-4, SOX2, and Nanog [381]. Besides mammosphere generation, CTH-B544 and CTH-B693 gained a stemness phenotype with increased expression of Oct4, SOX2, and Nanog promoting tumor progression; CTH cells were positively stained for SSEA4 which is associated with EMT and drug resistance [381]. SOX2, Nanog, and Oct4 expression was associated with poor differentiation, advanced cancer stages, and the worst outcomes in breast cancer patients [382]. Studies have implicated CD44 in breast cancer cell adhesion, proliferation, motility and migration, angiogenesis, and metastasis. Limited CD24 expression in breast cancer cells was shown to augment their growth and metastatic potential through a chemokine receptor response [381]. The CD44<sup>high</sup>/CD24<sup>low</sup> phenotype was recognized in CTH-B544 and B693 cells indicating a tumor-initiating phenotype similar to that of the highly tumorigenic breast cancer cells [383]. The existence of an intermediate state between epithelial and mesenchymal phenotypes is considered a hybrid E/M state which is associated with elevated cellular plasticity, migration, stem-cell-like properties, metastatic potential, and therapy resistance [367]. In CTH cells, the co-existence of vimentin and E-cadherin resembled a partial EMT hence ensuring their plasticity while preserving the same tumor-propagating potential [125]. Since in breast tumors CD49f was considered a marker for distant metastasis and recurrence, CD49f<sup>+</sup>/CD44<sup>high</sup>/CD24<sup>low</sup> CTH cells represented an aggressive phenotype which is associated with an increased risk for disease recurrence with poor clinical outcomes [384].

On the transcriptomic level, biopsy 693 overexpressed EGFR, CNDK2A, CCND1, SOX2, Oct4, and Nanog. It is known that EGFR promotes TNBC progression through JAK/STAT3 signaling [385], CNDK2A drives TNBC tumorigenesis [386], CCND1 has a prognostic significance in TNBC [387], and the three embryonic markers correlate with stemness, metastasis, tumor relapse, and poor clinical outcomes of TNBC [388]; therefore, we proposed that biopsy 693 maintains a tumor signature that is associated with an aggressive behavior predicting poor clinical outcome.

Studies reveal that the initiation of KSHV and EBV lytic cycles supported malignancies driven by the aforementioned oncogenic viruses [389,390]. HCMV persistence was established in CTH cells by detecting IE1 and pp65 throughout long-term cultures [125,126,209]. High-risk strains express

immediate-early (IE), early (E), and late (L) viral antigens including IE1 in agreement with a viral lytic cycle following the acute infection of permissive cells such as MCR5 cells. High-risk strains are detected in chronically infected cells, for instance CTH cells in our study, which is in line with the HCMV latency observed in Hodgkin's disease and Non-Hodgkin's lymphoma revealing the latent viral UL138 protein expression [391]. Nonetheless, a dynamic state of latency is recommended by novel transcriptomic studies. Since HCMV develops a complex relationship with the host, to define lytic and latency phases, several studies used the ratio of replicative and latency genes as a phase indicator [56,392]. To further highlight the role of the HCMV-IE1 gene, a study showed the potential of HCMV in regulating stemness in glioblastoma cells by specifically increasing SOX2 and Nestin, thus upregulating stemness and proliferation markers [393].

A study revealed the potential of combining GCV with certain chemotherapeutic agents to suppress EBV-positive NPC tumor growth [394]. In HPV-infected cervical cancer cells, cidofovir and cisplatin inhibited cellular proliferation, reduced E6 protein expression, and restored the activity of p53 [395]. A third study showed the effectiveness of anti-herpetic drugs, GCV and cidofovir, as single therapies or in combination with chemotherapy in treating KSHV-associated primary effusion lymphoma (PEL) [396]. Based on our results, the heterogeneity of HCMV strains including their distinct behavioral aspects had a major impact on CTH cells' response post-therapy. CTH-B544 cells were therapy sensitive whereas CTH-B693 cells displayed an aggressive behavior with lower sensitivity to PTX/GCV combination therapy. Generally, isolating distinct HCMV strains from tumors that possess potential prognostic biomarkers and behave differently depending on their own heterogeneity and various cell types may improve the diagnostic process and treatment options, provide effective follow-up strategies, and may be essentially pertinent in breast cancer pathophysiology and other adenocarcinomas, particularly of poor prognosis.

While our primary aim in this study was to investigate the potential link between breast cancer and the high-risk HCMV strains, we must not overlook the importance of the secondary goal of our research which was to examine the impact of these high-risk HCMV strains on the progression and clinical outcomes of GBM patients. Within the context of GBM, we presented the first experimental evidence for HCMV as a reprogramming vector, straight through the dedifferentiation of mature human astrocytes, and generation of CMV-Elicited Glioblastoma Cells

(CEGBCs) possessing glioblastoma-like traits. HCMV counterparts the progression of the perceived cellular and molecular mechanisms succeeding the transformation and invasion processes with CEGBCs involved in spheroid formation and invasiveness. Our study was conducted to assess the potential transforming capacities of HCMV-DB and BL following the HAs infection which were previously classified as high-risk transforming strains [125,126,241,397]. HAs infection with the high-risk HCMV-DB and BL strains resulted in a pro-oncogenic cellular environment and sustained growth of CEGBCs with soft agar colonies formation, unlike HAs infected with the low-risk HCMV-KM and FS strains that showed no transforming potentials and resulted in cell death in the long term cultures. CEGBCs displayed a “go and growth” phenotype in 2D monolayer cultures, dedifferentiated and displayed stemness as well as PMT features, and finally resulted in spheroid formation and invasion in 3D cultures. PGCCs appearance as well as cellular heterogeneity were previously allied to cultures of mammary epithelial cells infected with the high-risk HCMV strains [125,398]. Similar to HMECs transformed with the high-risk HCMV strains, around day 80 post-infection, we observed the appearance of dense cell aggregates, followed by the emergence of a wide array of morphologically distinct cells in HCMV-DB and BL cultures. We named these cells CMV-elicited glioblastoma cells (CEGBCs) with reference to the CMV-transformed HMECs (CTH) cells. PGCCs, NPC-like, neuron-like and mesenchymal-like cells were detected as well as filopodia, lamellipodia, and asymmetric cell division patterns. The described patterns could be representative of self-renewing cells undergoing diverse stages of the previously described giant cell cycle [125,398], although blastomere-like structures weren't so far detected as reported previously in CTH cells [125]. A replication-competent virus susceptible to reactivation from latency upon TPA treatment has been detected in CEGBC cultures. Activation of the Myc/EZH2 axis was observed in acute and sustained chronic infection with both high-risk HCMV strains. In agreement with EZH2 activation by HCMV, we observed a direct interaction between EZH2 and HCMV lncRNA4.9 transcript, likewise between EZH2 and cellular lncRNA HOTAIR transcript, a poor prognosis oncogenic factor for glioma patients. In line with EZH2 and HCMV involvement in our glioblastoma model, combination triple therapy (GSK343/GCV/TMZ) curtailed the growth of CEGBCs-derived spheroids. In vivo, all GBM tumor biopsies were found to harbor HCMV with enhanced EZH2 and Myc expression, possessing a strong positive

correlation between EZH2 and Myc expression as well as a strong correlation between EZH2/Myc and HCMV presence. Eleven HCMV-GBM strains were isolated from GBM tumors which acutely transformed HAs toward CEGBCs with increased EZH2/Myc expression that undergo dedifferentiation towards glioblastoma stem cells with spheroid formation and invasiveness capacities that could be curtailed by GSK343/GCV/TMZ triple therapy.

Among the mechanisms studied to transform HAs and promote disease progression in addition to poor prognosis in GBM, is the coupling of Myc and EZH2 overexpression as well as the depletion of retinoblastoma protein (Rb) which was observed in our study [336,399]. Although limited Myc upregulation and Rb downregulation were observed, none of the two low-risk HCMV-KM and FS strains transformed HAs as measured by soft agar colony formation in addition to the cell death observed in prolonged cultures. On the other hand, the high-risk clinical isolates HCMV-DB and BL can drive HAs towards oncogenic transformation *in vitro*. Our findings conform to the “astrocyte dedifferentiation theory” corresponding to glioblastoma origin [400–402]. In contrast to uninfected HAs, the distinct transcriptome profile including oncogenes, tumor suppressor genes and cell cycle genes facilitated the characterization of CEGBCs that possess a glioblastoma-like phenotype [403,404]. Stemness acquisition, commonly described in metastasis and poorly differentiated tumors [405–407], is in accordance with previous findings where GB-generated spheroids are composed of glioma stem cells (GSCs). The concomitant presence of the stemness marker nestin and HCMV-IE1 was detected in the spheroid structures generated from CEGBCs, as reported for nestin in the cell lines derived from GBM [408]. Highly motile Nestin/IE1-positive cells were spotted leaving the core which are similar to the neural-progenitor-like tumor cells detected in glioblastoma, especially the ones adopting the Lévy-like movement patterns [293,408]. The concomitant presence of viral proteins and nestin within transformed cells has been reported for the two herpes oncoviruses EBV and KSHV [409,410]. In agreement with enhanced CD44 and CD133 expression in CEGBCs, their expression in glioblastoma stem cells correlates with cell proliferation, intra-tumor heterogeneity, invasion and poor prognosis in CD44-expressing glioma [405,411]. The presence of vimentin<sup>+</sup>/CD44<sup>+</sup> cells in CEGBC cultures as well as the detection of stem cells expressing SOX2 and nestin confirms the PMT plasticity. In agreement with the proneural-mesenchymal plasticity described upon oncogenic stress activation highlighting

astrocyte plasticity/reactivity during tumorigenesis [370,412,413], a high invasive potential was observed in CEGBCs-DB compared to BL with increased mesenchymal traits indicating a more aggressive behavior that might drive therapeutic resistance.

Accumulated evidence highlighted Myc and EZH2 as key players in both oncogenesis and stemness. Myc stimulates EZH2 expression by activating the EZH2 promoter [328], repressing miR-26a [327], or directly suppressing miR-137. Bromodomain-4 protein (BRD4) positively regulates EZH2 transcription through Myc upregulation [330]. Myc activation was reported in glioblastoma progression, particularly in poor prognosis and therapy resistant-tumors [328,414]. EZH2 mediates proliferation, migration, and invasion in GBM. High-risk HCMV clinical strains DB and BL differentially induce Myc upregulation, and consequently stimulate EZH2 overexpression as well as CEGBCs induction, pointing toward the presence of Myc/EZH2/CEGBCs axis underlying the described results. Though, the interrelationship between HCMV and EZH2 is further complexed by the detection of HCMV lncRNA4.9 gene in CEGBCs which is in line with Rossetto et al. report [320]. Consistent with our data, the cellular lncRNA HOTAIR was described to interact with EZH2 in glioblastoma, thus linked to tumor dissemination, PMT, and drug resistance [414,415]. The noticeable detection of high lncRNA HOTAIR in the EZH2 IP samples corresponding to CEGBCs-DB explicates the aggressiveness of this particular high-risk HCMV strain, predicting poor prognosis. Indeed, EZH2-mediated stemness could underlie the appearance and maintenance of CEGBCs expressing a high degree of embryonic stemness, as EZH2 expression in astrocytes induced their dedifferentiation toward stem-like cells expressing nestin, SOX2, and CD133 [402]. Further, we reported the detection of HCMV in GBM tumor biopsies displaying enhanced EZH2, Myc, and Akt expression. HCMV-induced Myc and EZH2 expression along with the embryonic stem-like phenotype in the IE1-expressing CEGBCs could establish a significant model in the context of GBM. Since EZH2 and Myc have been implicated in tumor initiation and proven to impact glioblastoma appearance and development with the two high-risk HCMV DB and BL strains isolated from biological fluids (cervical swab and urine respectively), we evaluated EZH2/Myc expression and recovered HCMV strains directly from GBM biopsies thereby assessing their oncogenic potential. Eleven HCMV strains were isolated from GBM tumors (with unmethylated and methylated MGMT promoters). After HAs

infection, CEGBCs were generated with morphological features matching the previously described CEGBCs-DB and BL and led to the appearance of spheroids with invasiveness potential. HCMV-IE1 protein detection parallel to stemness markers and the upregulated Myc and EZH2 expression parallel to the detection of lncRNA4.9 gene, lncRNA4.9 and HOTAIR transcripts in cultures infected with the eleven HCMV-GBM strains recapitulates the previously observed molecular phenotype induced by HCMV-DB and BL strains. The expression of Myc was predominantly elevated in IE1-positive HAs. Altogether, HCMV strains are present in GBM tumors retaining tumor-promoting abilities, therefore considered as oncogenic strains.

Highlighting the critical role of EZH2 and HCMV in our glioblastoma model, the impact of EZH2 inhibitor (GSK343) and anti-HCMV drug ganciclovir (GCV) alone and in combination with TMZ was assessed. TMZ possessed a very limited effect on the growth of CEGBCs spheroids derived from HCMV-DB, HCMV-BL and the eleven HCMV-GBM strains. In agreement with our results, valganciclovir possessed a positive effect on glioblastoma tumors with an unmethylated or methylated MGMT promoter gene [416], potentially through its antiproliferative effect [417,418]. Although GSK343 single therapy had a limited effect on the growth of CEGBCs spheroids, its combination with TMZ enhanced the restriction of the CEGBCs spheroids growth derived from DB and BL, and to a lesser extent HCMV-GBM strains. EZH2 may modulate TMZ resistance where blocking EZH2 reverses TMZ chemosensitivity in GBM patients; an increased number of apoptotic cells were detected by knocking down EZH2 [419]. Although encouraging responses were detected post-dual therapy (GSK343/TMZ) in CEGBCs-DB and BL, and to a lesser extent from the eleven GBM HCMV strains, the triple therapy (TMZ/GSK343/GCV) was the most effective in CEGBCs derived from DB, BL, and the eleven GBM HCMV strains. Hence, triple therapy provides the foundation for a combinational therapeutic strategy to improve overall patient survival, reduce viral resistance, and lower drug toxicity.

While exploring the potential association between HCMV, BC, and GBM, we also recognized the significance of understanding how diverse HCMV viral strains may influence OC progression. Finally, we presented the experimental evidence for HCMV as a reprogramming vector that elicited human ovarian epithelial cells (OECs) transformation leading to the generation of “CMV-

transformed Ovarian cells” (CTO). Herein, we assessed the potential transforming capacities of the high-risk HCMV-DB and BL strains, following the OECs infection. The OECs infection with the high-risk HCMV-DB and BL strains resulted in a pro-oncogenic cellular environment and sustained growth of CMV-transformed OECs with soft agar colonies formation. The CTO cells dedifferentiated, displayed stemness as well as EMT-MET hybrid phenotype, and finally resulted in PGCCs generation and spheroid formation. HCMV presence accompanied by polyploidy, EZH2 upregulation, and malignant phenotype potentially confirm the transformation process. In vivo, 72% of HGSOC biopsies were found to harbor HCMV with elevated PGCCs count as well as enhanced EZH2 expression, revealing a strong correlation between HCMV, PGCCs, and EZH2 expression. Three HCMV-OC strains were isolated from EZH2<sup>high</sup> OC tumors that transformed OECs toward CTO possessing increased EZH2, Ki67Ag, and Myc expression parallel to polyploidy induction. The expression of the aforementioned markers and polyploidy were curtailed by EZH2 inhibitors therapy.

PGCCs play a fundamental role in tumor progression and in regulating tumor heterogeneity [115,420]. Accumulating evidence reveals the presence of PGCCs in OC, particularly the HGSOC, where PGCCs act as stem-like, self-renewing cells that are considered prognostic factors for OC [115,421]. In our study, CTO cells generated PGCCs, and were heterogeneous showing distinct morphological features including budding, filopodia, lipid droplets-filled cells, blastomere-like cells, and multinucleated cells that were previously detected in OC especially HGSOC [420,422–427] and reported upon HCMV infection of human mammary epithelial cells [125,126,397]. Our findings indicated that polyploidy harboring HCMV might induce the acquisition of a malignant phenotype via the giant cell cycling [118]. p53 and Rb inactivation have been correlated with tetraploidization in human tumors [428]. Indeed, p53 was shown to be mutated in more than 50% of human tumors, especially HGSOC; most of the p53 mutations acquired an oncogenic function. It’s worth mentioning that tumor-promoting viruses reduce p53 activity [429]. Studies have shown that the incidence of tetraploidy occurs in p53-deficient cells possessing prolonged DNA damage due to persistent telomere dysfunction [430]. p53 and Rb expression was decreased in CTO-DB and BL that showed high percentages of tetraploidization and decreased telomerase activity, in line with the telomere-driven tetraploidization induced by critically short telomeres with the

potential to promote tumorigenesis in early cancerous lesions [376]. Several HCMV products have been involved in the cellular transformation including IE1, IE2, pp65, US28, cmvIL-10, UL76, UL44, and UL84, etc. Such expression of HCMV gene products could impair the pathways of p53 and Rb [70,215]. HCMV-IE1, IE2, and UL97 allow the evasion of p53 and Rb [215]. Hence, the impaired p53 and Rb pathways in CTO cells was due to the transforming potential of HCMV contrasting the Ras, human telomerase reverse transcriptase (hTERT), and SV40-mediated transformation of human ovarian cells [431].

Cells possessing sphere-forming potentials were shown to reside in the malignant ascites of OC patients [432–434]. In OC, the aforementioned cells are strong contributors to tumor progression, metastasis, chemotherapy resistance, and disease relapse [433]. The spontaneous spheroid generation along with the high expression of Nanog and Oct4 in CTO-DB and BL is in line with the previously described OC cell phenotype [435]. Given their role in maintaining pluripotency and long-term self-renewal, the embryonic transcription factors Oct4 and Nanog are recognized as part of the stem cell signature that strongly correlates with spheroid formation, tumor initiation, and chemoresistance in ovarian cancer cells [435,436]. CD44 was highly expressed in CTO-DB and BL cells; it has been previously shown to drive the progression of several tumors [437,438], maintain stem cell quiescence, and promote EMT in OC [439]. Further, CD44 has been linked to the sphere-forming, self-renewing and tumor-initiating potential of OC cells [440]. The co-existence of vimentin and E-cadherin in CTO-DB and BL highlights the high cellular plasticity. EMT plasticity with EMT and MET alternately taking place was revealed during HGSOc progression where cells co-express epithelial and mesenchymal determinants [427,441,442]. Besides cellular plasticity, the hybrid E/M state promotes stem-like properties as well as metastatic and tumorigenic potential [367,443].

Upon infecting OECs with HCMV-DB and BL strains, IE1 and pp65 proteins were detected which is in line with the recent studies that have identified high expressions of HCMV-IE or pp65 in ovarian tumor samples that were associated with poor survival outcomes [304,444], suggesting that HCMV infection could potentially promote cancer progression. All in all, HCMV-induced EZH2 expression along with the embryonic stem-like phenotype and cellular plasticity in the IE1-expressing OECs/CTO cells could establish a significant model in the context of OC. Several

studies shed light on the existence of herpesviruses DNA and proteins in ovarian tissues that may hold potential in the process of OC tumorigenesis [304,444,445]. Herein, we reported the detection of HCMV in HGSOB biopsies displaying elevated PGCCs count as well as enhanced EZH2 expression. It is worth mentioning that, neither HPV nor EBV was detected in the eighteen tested HGSOB biopsies.

Three HCMV strains with a strong transforming potential, so called high-risk strains, were isolated from EZH2<sup>High</sup> HGSOB biopsies. After OECs infection, CTO cells were generated with morphological features matching the previously described CTO-DB and BL. Additionally, we evaluated EZH2 expression in the high-risk HCMV strains that were recovered directly from HGSOB biopsies thereby assessing their oncogenic and stemness potential. Unlike GSK-treated CTO, the expression of EZH2, Myc, and Ki67Ag was predominantly elevated in untreated CTO-HCMV-OC cells parallel to the PGCCs appearance. In summary, HCMV clinical strains reside in HGSOB biopsies retaining cancer-promoting potentials.

Targeting HCMV might have a vital role in treating OC [444]. Post-anti-CMV therapy, a remarkably high extended survival was observed in both newly diagnosed and recurrent glioblastoma patients [446]. Current vaccine candidates have focused on several HCMV antigens/epitopes such as gB, gH, pentamer complex, pp65 and IE1 [447,448]. Recently, CMV-specific immunotherapy including cytotoxic T lymphocyte (CTL) or dendritic cell (DC)-based vaccines has contributed to minimal successful outcomes in glioblastoma treatment [8,448]. In addition, using EZH2 inhibitors to specifically target ovarian tumors could ultimately improve patients outcomes [322]. Two inhibitors triggering EZH2 degradation (DZNep and YM281) exhibited potent efficacy in OC cell lines and xenografts [323]. GSK343 significantly induced apoptosis and inhibited the invasion of ovarian epithelial cells in 3D cultures which more closely mimics the tumor microenvironment in vivo [449]. In patient-derived glioma stem cells, GSK343 was shown to suppress the stemness traits [335]. Interestingly, in the present study, EZH2 inhibitors totally blocked HCMV replication. It's worth noting that the HCMV major immediate early promoter (MIEP) transcriptional repressor, growth factor independence1 (GFI1), is controlled by the EZH2-NDY1/KDM2B-JARID2 axis. Therefore, EZH2 inhibitors might result in an enhanced GFI1 expression which could block viral replication [450]. Hence, combinational

therapies including EZH2 inhibitors may prove to be a promising milestone in developing therapeutic strategies for ovarian cancer treatment.

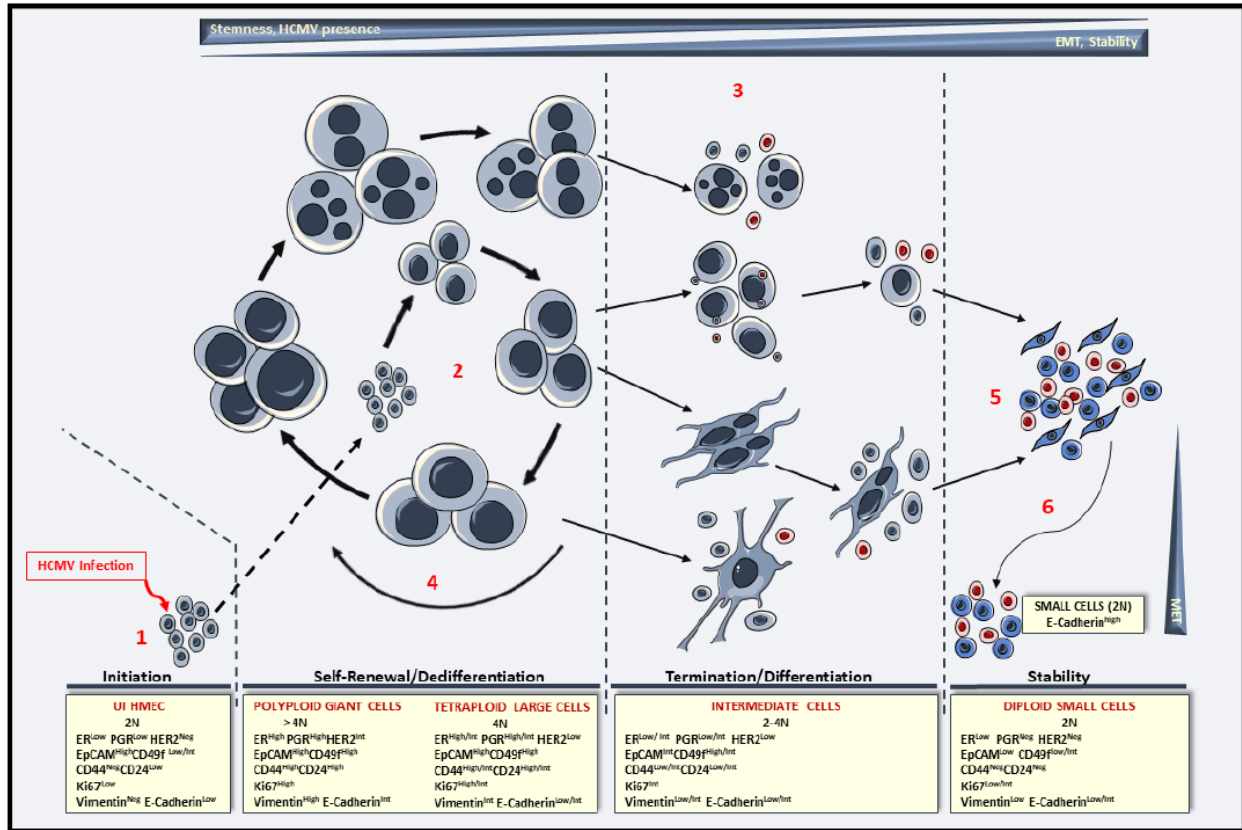

Overall, the existence of diverse strains expressing potential biomarkers and possessing various replication potentials in different tissues and/or cell types explain the distinct oncogenicity. So far, sixteen high-risk oncogenic clinical HCMV strains were isolated directly from tumor biopsies (breast cancer, N=2; glioblastoma, N=11; HGSOCs, N=3). These strains shared the same transforming potential. PGCCs were detected in the aforementioned cell cultures that were shown to highly express Myc and EZH2 pointing toward a potential link between HCMV, PGCCs, EZH2, and Myc. CTO and CTH cells dedifferentiated and revealed stemness as well as EMT traits. On the other hand, CEGBCs dedifferentiated and displayed stemness, PMT as well as invasiveness features. The phenotypic changes were similar in HCMV-infected ovarian and mammary epithelial cells. However, the difference was mainly the detection of high percentages of tetraploid cells in the CTO cultures compared to the >4N population detected in CTH cells. In both models, a high degree of cellular plasticity was detected knowing that ovarian and mammary epithelial cells are isolated from human glandular organs. Thus, discovering distinct viral strains will adjust the different adopted approaches to tumor diagnosis, prognosis, prevention, advanced treatment, as well as therapy monitoring and will enrich potential vaccine studies. In the forthcoming studies, it would be essential to sequence the isolated high-risk HCMV strains aiming to define the specific viral gene(s) that are responsible for driving the transformation process. Further, it is of high importance to conduct *in vivo* experimental studies since they can serve as a crucial bridge for extrapolating our findings to the patient context as well as translating the exact relevance of such models in the pathogenesis of breast cancer, GBM, and ovarian cancer. This could play a pivotal role in indicating and confirming HCMV as an oncogenic virus.

## Chapter 9

### 9. Conclusion

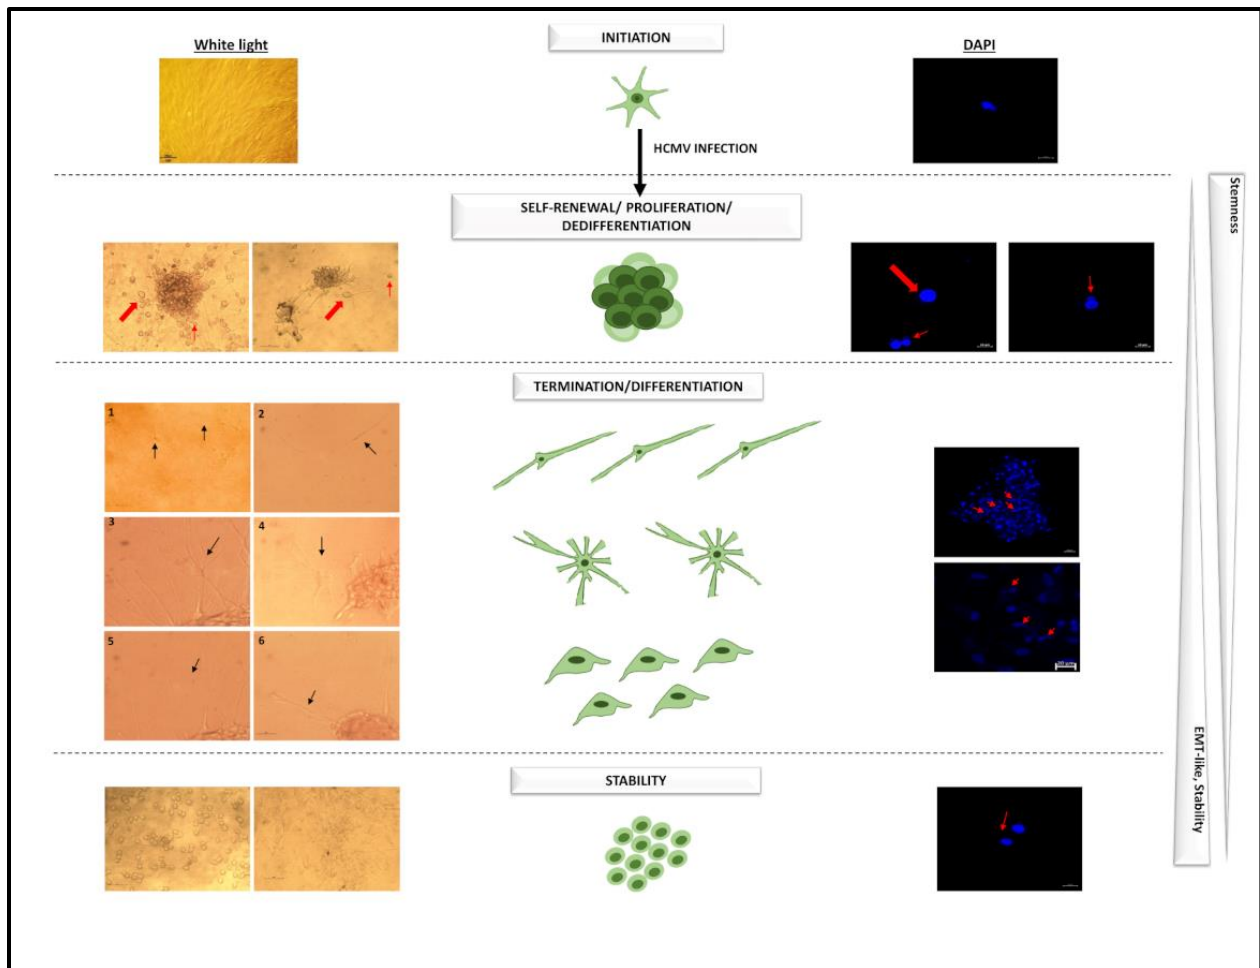

As a conclusion, our findings elucidate the concept of how HCMV is linked to breast cancer, glioblastoma, and ovarian cancer as depicted in the figures below (**Figure 53, Figure 54, and Figure 55**). The data that were provided proved that HCMV is not solely associated with oncomodulation; it is also recognized for its involvement in oncogenesis. The oncogenic and stemness signatures of the high-risk HCMV strains accentuate the oncogenic potential of HCMV in breast cancer, glioblastoma, and ovarian cancer progression and support the tumorigenic properties of EZH2 and Myc which might be highly pertinent in the pathophysiology of the aforementioned tumors. With respect to breast and ovarian cancer, HCMV triggered EZH2 and Myc expression, generated PGCCs, displayed dedifferentiating phenotypes with stemness features as well as hybrid EMT/MET phenotypes parallel to the existence of giant cell cycling. Further, HCMV induced a CEGBCs phenotype with tumor heterogeneity, proneural to mesenchymal plasticity, and embryonic-like stemness leading to spheroid formation and invasiveness in vitro and in GBM biopsies.

In accordance with the previous findings discussed, and considering that HCMV has been detected primarily within tumors correlating positively to poor prognosis, along with the potential influence of HCMV gene products on the regulation of tumorigenic pathways and processes associated with key cancer characteristics, and taking into account HCMV's wide tissue tropism, we deduce that HCMV harbors distinctive mechanisms that contribute to cancer progression.

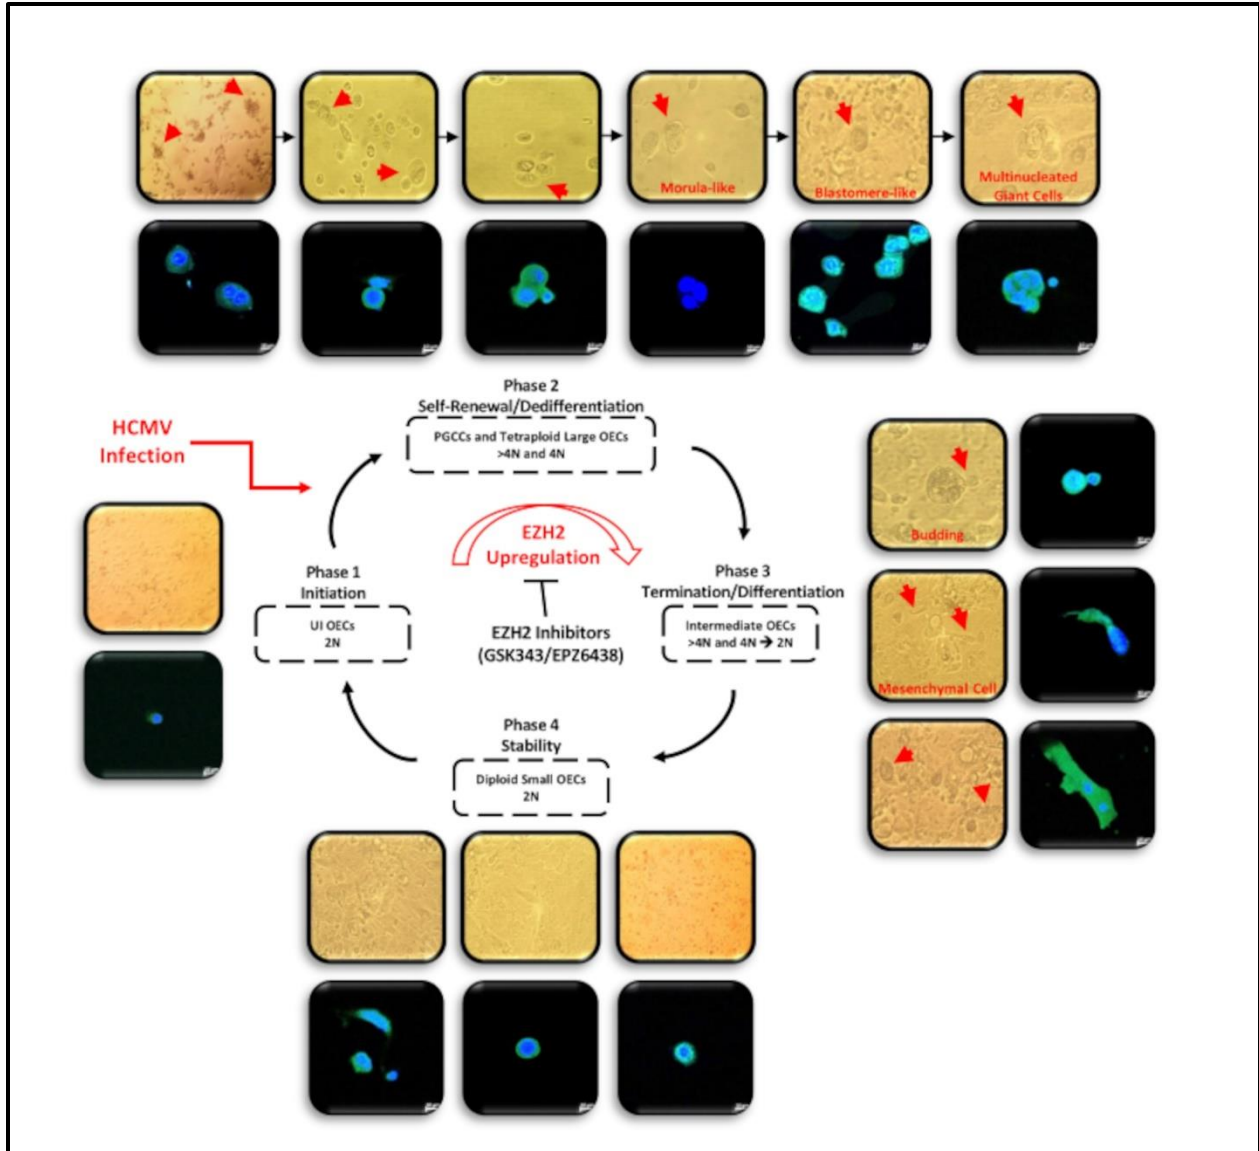

**Figure 53: Potential model depicting the course of events leading to the initiation of the giant cell cycle.**

In response to HCMV infection (1), the 2N human mammary epithelial cells (HMECs) enter the initiation phase of the giant cell cycle through endoreplication (2). Polyploid (>4N) cells in the dedifferentiation stage display a luminal-like phenotype with high to intermediate expression of epithelial and stemness markers. Cells directly bud from multinucleated or mononucleated giant cells (3) or alternatively continue endoreplication (4). The termination/differentiation step characterized by intermediate 2-4N cells profile gradually achieve stability into diploid 2N small cells (SCs) (5), where the latter are triple-negative with lower expression of epithelial and stemness markers. A small population of SCs could revert and show a mesenchymal-to-epithelial transition (6). A gradual decrease in HCMV presence is seen from left to right. Adapted from Nehme et al [125].

**Figure 54: Glioblastoma generation scheme.**

The scheme illustrates the four phases of the CEGBCs cycling including initiation, self-renewal, proliferation, and dedifferentiation, termination/differentiation, and stability. Large red arrows showed the large cells and PGCCs; Small red and black arrows showed the intermediate/small heterogeneous cells. In the termination/differentiation phase, NPC-like (1, 2), neuron-like (3, 4), and mesenchymal-like (5, 6) cells were detected.

**Figure 55: A schematic representing the giant cell cycling following HCMV infection of OECs.**

Giant cell cycle representing four distinct phases including initiation, self-renewal, termination and stability. Upon HCMV infection, the 2 N OECs go into the initiation phase through endoreplication. Polypliod cells (> 4 N) and tetraploid cells (4 N) generate in the self-renewal/dedifferentiation stage due to HCMV infection and the subsequent EZH2 upregulation. Cell budding takes place from multinucleated or mononucleated giant cells generating intermediate 2–4 N OECs during the termination/differentiation phase. Intermediate OECs gradually reach stability and are converted into diploid small OECs (2 N).

Future studies, with more detailed analyses of target genes within the CMV-transformed cells namely, CTH, CEGBCs, and CTO cells and their corresponding response to inhibitors may establish new avenues to understand the complex pathogenesis of breast cancer, glioblastoma, and ovarian cancer. Additionally, large-scale experiments are highly encouraged to further validate our findings. Meanwhile, the presented data provides new insights into the oncogenic role of HCMV in cancer progression, thereby uncovering novel targeted therapeutic approaches and innovative clinical interventions that will improve cancer patient outcomes and their overall survival rates.

Coronaviruses (CoVs) are highly variable single-stranded RNA viruses susceptible to genetic mutations and recombination. They include pathogens like SARS-CoV, MERS-CoV, and the highly infectious SARS-CoV-2, responsible for the COVID-19 pandemic. Severe outcomes of COVID-19 are linked to older age and compromised immune systems, often involving a cytokine storm marked by excessive inflammation. The molecular processes governing coronavirus infection encompass interactions between the virus and host, affecting viral entry, replication, escape, and immune control. Exploring coronavirus infections and COVID-19 from an epigenetic perspective may lead to altered gene expression, potentially limiting infection. Clinical trials of epigenetic therapies, approved epigenetic agents, and combining antivirals with epigenetic drugs are viewed as effective strategies for controlling viral replication and excessive inflammation.

# Management of epigenomic networks entailed in coronavirus infections and COVID-19

Ranim El Baba<sup>1,2</sup> and Georges Herbein<sup>1,3\*</sup>

## Abstract

Coronaviruses (CoVs) are highly diverse single-stranded RNA viruses owing to their susceptibility to numerous genomic mutations and recombination. Such viruses involve human and animal pathogens including the etiologic agents of acute respiratory tract illnesses: severe acute respiratory syndrome coronavirus (SARS-CoV), Middle East respiratory syndrome coronavirus (MERS-CoV), and the highly morbid SARS-CoV-2. Coronavirus disease 2019 (COVID-19), an emerging disease with a quick rise in infected cases and deaths, was recently identified causing a worldwide pandemic. COVID-19 disease outcomes were found to increase in elderly and patients with a compromised immune system. Evidences indicated that the main culprit behind COVID-19 deaths is the cytokine storm, which is illustrated by an uncontrolled over-production of soluble markers of inflammation. The regulation process of coronavirus pathogenesis through molecular mechanism comprise virus-host interactions linked to viral entry, replication and transcription, escape, and immune system control. Recognizing coronavirus infections and COVID-19 through epigenetics lens will lead to potential alteration in gene expression thus limiting coronavirus infections. Focusing on epigenetic therapies reaching clinical trials, clinically approved epigenetic-targeted agents, and combination therapy of antivirals and epigenetic drugs is currently considered an effective and valuable approach for viral replication and inflammatory overdrive control.

**Keywords:** Coronavirus, SARS-CoV, MERS-CoV, SARS-CoV-2, COVID-19, Epigenetic, Inflammation

## Background

Coronaviruses are non-segmented, enveloped viruses with a positive-sense single-stranded RNA genome belonging to Coronaviridae family [1–3]. CoVs share similar genome organization, but differ phenotypically and genotypically [4, 5]. High frequency of RNA recombination, RNA-dependent RNA polymerase (RdRp) fickleness, and the bulky genomes for RNA viruses are considered leading factors for CoVs' diversity [5]. Humans are infected by seven CoVs, including HCoV-

229E and HCoV-NL63 belonging to Alphacoronavirus; HCoV-OC43 and HCoV HKU1 belonging to Betacoronavirus lineage A; these four viruses are known to be endemic [4–6]. Three human coronaviruses (HCoVs) caused epidemics expressing high morbidity and mortality rates: SARS-CoV belonging to Betacoronavirus lineage B, MERS-CoV or HCoV-EMC belonging to Betacoronavirus lineage C, and the 2019 novel coronavirus 2019-nCoV/SARS-CoV-2 [6–8].

SARS-CoV emerged in Guangdong Province, China, in February, 2003 [9, 10]. It resulted in 8098 human infections and 774 deaths, and it disseminated into 37 countries [3, 11]. In 2012, MERS-CoV was initially detected in the Kingdom of Saudi Arabia revealing 2494 confirmed infected cases and 858 mortalities. It was spread

to 27 additional countries [3, 12]. While the MERS-CoV outbreak has been mostly limited to the Middle Eastern region, it is likely that more re-emerging HCoV's might endanger the global communal health condition. SARS-CoV-2 was identified in late December, 2019 in Wuhan, China [8]. The World Health Organization (WHO) declared that COVID-19 was listed as the sixth Public Health Emergency of International Concern (PHEIC), implicating that it may pose risks to various countries and entail an international response [8, 13, 14]. A situation report showed COVID-19 data as received by WHO in 9 June 2020: 7,039,918 confirmed cases and 404,396 deaths were globally reported in American, European, Eastern Mediterranean, Western Pacific, South-East Asia, and African regions [15]. However, underestimating COVID-19's burden was due to the fact that patients with mild COVID-19 symptoms or asymptomatic patients might not seek medical care for proper diagnosis.

As outbreaks can ensue rapidly worldwide, it is quite necessary to emphasize on novel therapeutic approaches. Although investment in biomedical and pharmaceutical research has increased significantly, the annual number of new treatments approved by the Food and Drug Administration (FDA) has remained relatively limited [11, 16]. Generally, the available treatment strategies for emerging coronavirus' strains, that led to significant pandemics, are inadequate to effectively advance patient's outcome [17]. These strategies have been less successful for RNA viruses compared to DNA viruses as the former mutates at a higher rate resulting in drug resistance [4].

Yet, HCoV's potentially influence the host's epigenome, and this will aid in discovering new targets for therapeutic interventions to gain more insights for the development of antiviral therapeutics and vaccines [9, 18]. The primary objective of this review is to evaluate the epigenetic mechanisms involved in HCoV's infection and to highlight on epigenetic therapies in order to reduce peak incidence and global deaths resulting from HCoV's outbreaks worldwide.

**Epigenetic mechanisms at work in coronavirus replication**  
**Epigenetic regulation of coronavirus replication**

The genome of SARS-CoV-2 is composed of a single-stranded positive RNA of 29 kb; it is considered the largest of all RNA virus genomes (Fig. 1a) [3, 11]. So far, 14 open reading frames (ORF) have been described in the SARS-CoV-2 genome [11, 19]. SARS-CoV-2 genome encodes for viral proteins involved in viral replication named non-structural proteins (Nsp) including the replicase complex coded by ORF1ab, and structural viral proteins involved in viral assembly including the spike (S), envelope (E), membrane (M), and nucleocapsid (NP) protein [3, 11]. The S protein, a class I fusion glycoprotein, forms homotrimers bulging in the viral surface facilitating the viral envelope binding to host cells by attraction with angiotensin-converting enzyme 2 (ACE2). This transmembrane protein is cleaved by the host cell furin-like protease into 2 subunits labeled S1 which binds to the receptor on the host cell surface and S2 is responsible for fusion activity [1, 3]. Hence, disparities in the S protein would directly impact the viral

biological characteristics including pathogenicity and antigenicity. Spike protein has been considered as the ultimate target for COVID-19 immunotherapies, and this is based on SARS-CoV and MERS-CoV preceding evidence. Recently, studies have found that SARS-CoV S protein induced polyclonal antibody responses and counteracted SARS-CoV-2 S-mediated entry into host cells, thus favoring the use of this ideal molecular target for vaccination and immunotherapies [20]. Even though SARS-CoV-2 crisis is noteworthy, referring to HCoV's data is eminently required since HCoV and SARS-CoV-2 share genomic and biological properties.

#### **Epigenetic regulation of HCoV entry**

ACE2, a significant player in the **renin-angiotensin system** (RAS), was recognized as vital factor that attaches to spike protein and eases SARS-CoV-2 binding and host cell entry. Early studies have shown that this receptor acts as a protective mechanism to block the early stages of COVID-19 [11, 21]. ACE2 is significantly expressed in the lower respiratory tract such as type II alveolar cells (AT2) of the lungs, upper esophagus, and stratified epithelial cells, as well as in kidney proximal tubule cells, bladder urothelial cells, absorptive enterocytes, cardiomyocytes, and cholangiocytes. Such cellular outspreading elucidates the consequences of SARS-CoV-2 infection that is not only limited to respiratory disorders but also to kidney, liver, heart, and gastrointestinal tract illnesses [19]. Sirtuins, a family of nicotinamide adenine dinucleotide (NAD)<sup>+</sup> dependent deacetylases, play an important role in cellular homeostasis [22]. Silent information regulator T1 (SIRT1), a histone deacetylase (HDAC) class III, is a key regulator of ACE2 levels via binding to its promoter [23]. In fact, resveratrol a well-known activator of SIRT1 increases the ACE2/angiotensin 1-7 (Ang1-7)/Mas receptor (MasR) axis parallel to the downregulation of the Angiotensin II receptor type 1 (AT1R) expression belonging to the prorenin receptor (PRR)/ACE/angiotensin II (Ang II)/AT1R axis [24–28]. Although it was not shown so far that SIRT1 increases SARS-CoV-2 entry into the cell due to increased ACE2 expression, COVID-19 patients with high levels of ACE2 have a better prognosis probably due to decreased hyperinflammation [28–30]. Similarly, SIRT1 could impact viral entry of SARS-CoV and HCoV-NL63 which also use ACE2 for viral entry [31]. Foremost host cellular receptors significantly utilized by other HCoVs for entry and viral replication are aminopeptidase N (APN) by HCoV-229E, dipeptidyl peptidase 4 (DPP4) by MERS-CoV and 9-O-acetylated sialic acid by HCoV-OC43 and HCoV-HKU1 [5, 6, 32, 33]. Any mutations in human APN cell surface receptor will directly inhibit virus-receptor interaction [33]. Promoter hypermethylation downregulates APN gene expression and azacitidine (5-

azaC) induces APN protein expression [34]. In melanoma cells, the combination of HDAC inhibitor CHR-3996 and APN inhibitor tosedostat activated synergistically NF- $\kappa$ B [35]. Glucocorticoids directly upregulate the DPP4 gene expression in macrophages due to the presence of two GC-binding motifs in the DPP4 gene promoter [36]. Therefore, the cell surface expression of HCoV entry receptors can be modulated by epigenetic drugs which could be used to discover new therapeutic approaches to curtail HCoV infections.

#### **Epigenetic regulation of HCoV replication and transcription**

Coronaviruses employ a multisubunit machinery for replication and transcription. The RdRp, also known as Nsp12, catalyzes the synthesis of viral RNA and thus plays a central role in the replication and transcription cycle of SARS-CoV-2, possibly with the assistance of Nsp7 and Nsp8 as cofactors [37]. Nsp7 interacts with the 7SK small nuclear ribonucleoprotein (7SK snRNP) complex comprising La-related protein (LARP7), methyl-phosphate capping enzyme (MEPCE), and hexamethylene bisacetamide inducible protein (HEXIM1). This complex sequesters positive transcription elongation factor (P-TEFb) which is critical for the replication of several viruses including herpesviruses, human immunodeficiency viruses (HIV), human T-lymphotropic virus (HTLV), human adenovirus (HAdV), influenza A virus and Dengue virus (DENV) [38]. The interaction between Nsp7 and P-TEFb will result in the release of the active form of P-TEFb known to bind bromodomain-containing protein 4 (BRD4); similar interaction has been reported previously for HIV Tat and P-TEFb. Interestingly, bromodomain and extra-terminal motif (BET) inhibitors such as JQ1, I-BET, I-BET151, OTX015, UMB-136, MMQO, CPI-203, RVX-208, PFI-1, BI-2536, and BI-6727 induce P-TEFb release and have been reported to be latency reversal agents in HIV infection [39]. Nsp14, a 3'-5' exonuclease, is critical for coronavirus RNA synthesis [40]; Nsp14 interacts with SIRT5 acting as a weak deacetylase but with desuccinylase and demalonylase activities regulating several metabolic pathways [41]. Recently, SIRT5 inhibitors have been developed [42]. Nsp13 helicase/triphosphatase participate in the release of newly synthesized RNA strand and thus the production of infectious viral particles [43]. Since p300 expression is under HDACs' control [44], helicases such as Nsp13 might be under the control of p300 and thereby HDAC inhibitors might interfere with coronavirus replication. The Nsp3-Nsp4-Nsp6 complex is also involved in viral replication. Remarkably, Nsp4 interacts with HDAC2, and this could emphasize the role of epigenetic therapies in blocking HDAC2 [45]. Nsp10 is

essential for the RNA cap methyl transferase of Nsp16. During RNA capping, Nsp16 methyl transferase activity could be blocked by methyltransferase inhibitors such as sinefungin, dAPPMA 2'-O MTase inhibitors, aurintricarboxylic acid and inhibitor 7 [46]. Finally, Nsp15 is a uridine-specific RNA endonuclease which has been shown to cleave a highly conserved RNA structure in the 3' non-translated region of the SARS virus [47]. Most recurrent transcription regulating sequence (TRS) related to MERS-CoV is TRS2. Generally, MERS-CoV transcribes 11 subgenomic mRNAs, including various ORFs translating polypeptide chains and fusion proteins. Unlike MERS-CoV, SARS-CoV includes TRS3 that exists also in SARS-CoV-2. SARS-CoV possesses several accessory proteins (AP), which are translated directly from mRNAs. SARS-CoV-2 grants comparative differences in transcription and subgenomic mRNAs translation compared to other beta-coronavirus. SARS-CoV-2 initiates transcription in 20 TRS sites, transcribing much more forms of subgenomic mRNAs than SARS-CoV and MERS-CoV; this could correlate to the severity and high infectivity of COVID-19 on host patients. SARS-CoV-2 produces around nine forms of fusion proteins, with higher concentrations of Nsp12, Nsp3, Nsp5, and AP12 [48].

#### **Epigenetic regulation of HCoV protein maturation**

Newly synthesized viral polyproteins are cleaved by viral proteases, namely, the 3C-like protease (3CLpro) and the papain-like protease (PLpro) [49]. ORF1a encodes the two cysteine proteases, 3CLpro and PLpro. While PLpro cuts the first three cleavage sites of its polyprotein, 3CLpro is responsible for cleavage of the residual 11 locations resulting in release of a total of 16 Nsp in both SARS-CoV and MERS-CoV [45]. Upon comparing SARS-CoV and SARS-CoV-2, correspondences have been detected in 5'UTR and 3'UTR regions, protease cleavage positions and amino acid conformation of both structural and non-structural proteins. Yet, the number of spike precursors and specificity of accessory proteins differ in SARS viruses. SARS-CoV processes two spike precursors (S1p and S2p), while SARS-CoV-2 and MERS-CoV produce only one. AP11 is characteristic for SARS-CoV, whereas SARS-CoV-2 translates a specific accessory protein AP12 [48]. Nsp5, the coronavirus 3CLpro, is critical for the maturation of non-structural SARS-CoV-2 proteins. Actively, 3CLpro binds to HDAC2 and tRNA methyl transferase 1 (TRMT1) resulting in their cleavage [45]. Thus, 3CLpro mimics HDAC2 inhibitor and might therefore facilitate viral and/or cellular gene expression in infected cells. TRMT1-catalyzed tRNA modifications are required for redox

homeostasis to ensure proper cellular proliferation and oxidative stress survival [50]. Since TRMT1 is cleaved by 3CLpro, SARS-CoV-2 might interfere with tRNA methylation in infected cells. Numerous drugs have been reported to inhibit the activity of 3CLpro including the anti-HIV drug lopinavir [16]. The structural viral proteins (NP, M, E, and S) participate in the formation of new virions across the endoplasmic reticulum. SIRT1 activation following treatment of the infected cells with resveratrol results in decreased viral replication [51]. The viral envelope E binds to BRD2 and BRD4 and could be the target for BET inhibitors [39, 45]. Therefore, blocking SARS-CoV-2 structural proteins' maturation could result firstly from the usage of SARS-CoV-2 protease inhibitors to annihilate the viral polyprotein cleavage by 3CL pro and/or PLpro, and secondly from the epigenetic treatments to decrease the amount and/or activity of structural viral proteins.

#### **Epigenetic-targeted therapies controlling coronavirus replication**

Understanding fundamental elements of epigenetic regulation is progressively contributing to concepts of viral epigenetic therapeutics. Epigenetic therapies are among the most active areas of research and this is because of their potential specific targeting mechanisms compared to the conventional therapies. Manipulating gene regulatory networks using epidrugs could be associated with a risk generating from the systemic effect of such therapies. Yet, knowing that HCoVs including SARS-CoV-2 may infect more than one cell type it is advantageous to rely on systemically acting agents. Besides, some proposed epigenetic treatments can be site-directed and consequently minimize unwanted systemic risk. Furthermore, it is imperative to spotlight the SARS-CoV-2 direct RNA sequence data including RNA modifications, the viral transcriptome and epitranscriptome as it could anticipate novel-targeted strategies for the management of SARS-CoV-2 infection [52]. Antiviral therapies targeting the pathogen itself act by inhibiting enzymes responsible for viral genome replication, the viral assembly process, and preventing viral entry by blocking the virus-host receptor binding. Remdesivir, favipiravir, ribavirin, galidesivir, and its salt form (BCX-4430) targeting RdRp; ritonavir and darunavir targeting viral proteases (3CLpro or PLpro) in addition to camostat mesylate which is a serine protease inhibitor directly acting on SARS-CoV-2. Moreover, the FDA approved lopinavir/ritonavir as a target of the coronavirus protease enzyme and arbidol (umifenovir) targeting ACE2 and S protein showed efficacy against SARS-CoV-2 as well as chloroquine which possesses an antiviral and an anti-inflammatory effect [16]. In the primary stages of SARS-CoV epidemic, an empirical treatment of broad spectrum antiviral agents and immunosuppressive

doses of steroids were used along with the supportive treatment [53]. Despite the available treatment options, studies documenting the therapies' efficacy are lacking especially for the SARS-CoV-2 outbreak [11, 54–56]. Nevertheless, extending the choices of treatment by generating epigenetic therapies would provide a real improvement to healthcare community struggling to cope during an outbreak of emerging viral infections (Table 1). Histone deacetylases (HDACs) resemble a main epigenetic target for the treatment of viral infections [64, 65] (Fig. 1b). Hence, HDACs class III such as SIRT1 and resveratrol have been previously described as antiviral effectors [22]. Resveratrol was found to modulate SIRT1 activity (SIRT 1,2,3,5) especially as a SIRT1 activator, 5' AMP-activated protein kinase (AMPK), protein kinase C, NF-kB, p53, activator protein 1 (AP-1), early growth regulator 1 (EGR-1), sterol regulatory

element-binding protein 1 (SREBP-1), and DNA methyltransferase (DNMT)1 thus targeting the regulation of viral infection [22, 57]. Significant downregulation of apoptosis induced by MERS-CoV, prolonged cellular survival post-MERS-CoV infection, potential decrease in viral NP protein expression, and decreased viral replication were detected after resveratrol administration [51]. Besides HDACs class III, the inhibition of the class II HDAC2 is achieved by the approved drug valproic acid (VPA) and the pre-clinical candidate apicidin [45, 59]. VPA displayed minimal control of SARS-CoV-2 growth regardless of drug concentration along with high cytotoxicity levels [45]. In addition to VPA and apicidin, HDAC inhibitors include the broad spectrum trichostatin A (TSA) which reduced the pro-inflammatory mediator's production, MS-275, and depsipeptide [63, 66, 67]. Other potent HDACi such as vorinostat or

**Table 1** Epigenetics involved in coronavirus infection and their therapeutic control

Epigenetic drug target	Antagonism "inhibitors"	Potential outcome	Combination therapy(few require clinical validation)	
HDAC	Pan-HDAC class I and II	VPA	Affecting inflammatory functions and interferon response [45].	VPA + antivirals (remdesivir, ribavirin, favipiravir, galidesivir) or (rapamycin, selumetinib, trametinib)
		TSA	Reduced pro-inflammatory mediator's production and increased IL-10 production [55].	or prostatin TSA + antivirals or (rapamycin, selumetinib, trametinib)
		Vorinostat (SAHA)	Diminished genomes initiating gene replication, and induced the expression of cellular proteins responsible for viral inhibition [57].	SAHA + antivirals or (rapamycin, selumetinib, trametinib) or prostatin or BIX-01294 or DZNep
	All HDAC classes including class I, II, and IV	Panobinostat	Affecting EGFR/HER2 signaling, MAPK signaling, PI3K-Akt, and NFκB pathway [58].	Panobinostat + antivirals or (rapamycin, selumetinib, trametinib)
	Belinostat and domatinostat	Enhanced TGF-β expression [58].	Belinostat or domatinostat + antivirals or (rapamycin, selumetinib, trametinib)	
HKMT	Pan-HKMT EZH2	DZNep	Attained cellular antiviral state and reduced viral yields [57].	DZNep + vorinostat
	HKMT G9a	BIX-01294	Enhancing antiviral state [57].	BIX-01294 + vorinostat
HMT	Suv39H1	Chaetocin	Permanent cell cycle arrest and RNA transcript blockage [59].	
		Anacardic acid, MG149, C646	Suppressed IL-6 levels [60, 61].	
DNMT	Resveratrol	Decitabine (5-azadC)	Down-regulation of apoptosis, decrease in (N) protein expression, and RNA viral replication antagonism [51].	5-azadC + antivirals or (rapamycin, selumetinib, trametinib)
		Azacitidine	Counteracting hyper-inflammation: lowering pro-inflammatory cytokines (TNF-α, IL-6, IL-1β) and chemokines, inducing IL-10 marker and TGF-β [58].	Azacitidine + antivirals or (rapamycin, selumetinib, trametinib)
			Viral mimicry [62].	
BET proteins (BRD4)	Clinical	ABBV-744, CPI-0610, RVX-208	BRD4 inhibition boosts a potential innate immune response, blocks viral attachment, induces DNA damage response (DDR), decreases viral replication, and arrests cell-cycle with no apoptotic signs [63].	
		Preclinical	dBET6, JQ-1, MZ1	

suberanilohydroxamic acid (SAHA), belinostat, romidepsin, and panobinostat were already used for the treatment of several cancers such as T cell lymphoma and relapse of multiple myeloma [68–70]. Knowing that viruses depend on host's epigenetic machinery, some epigenetic drugs used in cancer therapies were shown to give a potential broad spectrum antiviral action against novel emerging viruses. The histone methyltransferases-enhancer of zeste homolog 2/1 (HMT EZH2/1) inhibitors have the ability to attain cellular antiviral state and reduce viral yields instead of inducing activation [68, 71]. A pan-HKMT antagonist, 3-deazaneplanocin-A (DZNep), prove to be therapeutically superior to BIX-01294 which antagonizes HKMT G9a [71]. Chaetocin is a fungal mycotoxin which inhibits HMT Suv39H1, promotes permanent cell cycle arrest, and RNA transcript blockage [72]. Chaetocin is contraindicated with SAHA and JQ-1 as it causes cytotoxicity [73]. On the contrary, a possible synergism was revealed combining BIX-01294 with vorinostat and DZNep with vorinostat [71]. BRD4, a chief gene expression regulator, is involved in recognizing and modifying histone acetylation. Inhibition of BRD4 exhibits an effective antiviral effect against a wide range of RNA and DNA viruses by boosting a potential innate immune response, blocking viral attachment, inducing DNA damage response (DDR), decreasing viral replication, and arresting cell-cycle with no apoptotic signs. Bromodomain and extraterminal protein inhibitors are subdivided into clinical (ABBV-744, CPI-0610, RVX-208) and preclinical (dBET6, JQ-1, MZ1) candidates [45, 74]. By hindering the communication of BRD4 and transmembrane E protein, JQ-1, and dBET6 effectively inhibit the replication of SARS-CoV-2 genome [45, 75]. JQ-1 exhibited a potential viral inhibition at low doses; dBET6 expressed lower cytotoxicity levels than JQ-1. Knowing that the bromodomain and extraterminal protein inhibitors possess varying cytotoxicity further drug assessments must be performed prior patient use [45].

#### Epigenetic regulation of cellular and immune landscape during coronavirus infection

##### Cellular and immune landscape during coronavirus infection

In the course of viral infections, innate immune cells initiate a transcriptional signal that is cell and stimulus specific. Several main performers of innate immunity, such as signal transducer and activator of transcription 1 (STAT1), myeloid differentiation primary response gene 88 (MyD88), *Toll-like receptor* (TLR)4, TLR7, and TLR3/TIR-domain-containing adapter-inducing interferon-beta (TRIF) diminish infection severity during HCoV infection in vivo. Moreover, interferons (IFN-alpha, IFN-beta, IFN-gamma) which are regulated by histone marks aid in controlling HCoV infections in vivo and in vitro. IFN and tumor necrosis factor (TNF) are the primary

response genes of the innate immune system whose promoters show poised promoter features. H3K4me3, H3K27me3, and H3K9me2 are responsible for modulating the activation of the main player IFN. H3K9me2, a repressive histone mark, contributes to DNA methylation and heterochromatin formation and hence stopping histone tail acetylation by recruiting the transcriptional repressor of the heterochromatin protein 1 family. H3K4me3, a histone modification enriched in promoter regions, regulates Toll-like receptors (TLRs). As a result, IFN and innate immune responses are subject to epigenetic regulation mediated by specific epigenetic marks, the operation of histone modification enzymes, DNA methylases, and chromatin remodeling complexes. CoVs have progressed genetic functions that antagonize or delay pathogen recognition as well as IFN sensitive gene (ISG) effector functions. Upon the activation of danger sensors, dendritic cells (DCs), and macrophages a temporal and spatial response is epigenetically initiated. The ability of their epigenome to change within minutes after a stimulus is essential for initiating a speedy antiviral host response and to ensure a persistent/specific defense response. Hence, epigenetic mechanisms are responsible guaranteeing a functional and highly regulated host response beyond the initial activation wave [18, 76]. Several epigenetic factors were shown to be effective in the activation of immune responses: recruitment of transcription machinery, prevention of undesired expression of compelling mediators, and repression or stimulation of secondary gene programs [18]. Upon utilizing chromatin immuno-precipitation (ChIP) PCR approaches, it is possible to determine differential occupancy of histone marks at the promoters of ISG genes. During SARS-CoV infection, the promoter regions of ISG genes had more histones with active marks of H3K4me than the repressive H3K27me3 mark, therefore favoring open chromatin and promoting active transcription and ISG expression. MERS-CoV infection of Calu3, a continuous human airway epithelial cell line, resulted in increased levels of H3K27me3 and depletion of H3K4me3 occupancy at the promoter regions of subsets of specific ISGs. These viruses favored a closed chromatin conformation that inhibits ISG expression, which rather was regulated by epigenetic control mechanisms [9, 18, 76]. Thus, the setting of histone methylation marks could be different in two close CoV members, namely SARS-CoV and MERS-CoV.

Acute respiratory distress syndrome (ARDS) is a common immunopathological event for SARS-CoV, MERS-CoV, and SARS-CoV-2. A massive cytokine storm is considered as one of ARDS' principle mechanisms which is the chief death cause of COVID-19 in addition to MERS-CoV and SARS-CoV severe diseases [14]. During the cytokine storm, pro-inflammatory cytokines (IL-1 $\beta$ ,

IL-6, IL-12, IL-18, IL-33, TNF- $\alpha$ ) and chemokines (CCL2, CCL3, CCL5, CXCL8, CXCL9, CXCL10) are up-regulated by effector cells in SARS-CoV infection linked with respiratory distress [14, 77–79]. Unlike the pro-inflammatory cytokine IL-6, the anti-inflammatory Th2 cytokine TGF- $\beta$  is not overproduced in COVID-19 patients [77]. Augmented levels of IL-2, IL-6, IL-7, IL-10, granulocyte-colony stimulating factor (G-CSF), TNF- $\alpha$ , IFN- $\gamma$ -inducible protein 10 (IP10), macrophage inflammatory protein 1- $\alpha$  (MIP1A), and monocyte chemoattractant protein (MCP1) were associated with COVID-19 severity; a cytokine outline favoring secondary hemophagocytic lymphohistiocytosis (sHLH) [80, 81]. Poor prognosis of SARS-CoV-2 infected patients can be forecasted by SARS-CoV-2 viral load which is concomitant with cytokine storm caused by the extremely high IL-6 levels [82]. Older, chronically ill and immunocompromised patients are expected to be more susceptible to hyperinflammation. Demethylation of IFN-regulated genes, NF- $\kappa$ B, and key cytokine genes favors the expression of proinflammatory cytokines and chemokines thus increasing cytokine storm incidence [83]. As a result, minimizing IL-6 plasma concentrations and controlling ACE2 gene epigenetically might be a target for prevention and therapy in COVID-19 [82, 83]. In contrast to SARS-CoV-2, delayed serum levels of IFN, IL-1 $\beta$ , IL-6, IL-8, CCL-2, CCL-3, CCL-5, and IL-2 were detected in MERS-CoV-infected patients. Recent data revealed that pro-inflammatory cytokines (IL-6) and chemokines (IL-8, CXCL-10, and CCL5) responses were elevated in severe MERS-CoV cases [14, 78]. Low levels of the anti-inflammatory cytokine IL-10 was seen in confirmed SARS cases with severe disease. It is noteworthy that SARS-CoV infects monocyte-macrophages, DCs, and T cells which produce IL-10 [78]. In addition to the role of immune cells, the immune landscape in the lung of COVID-19 patients can also be shaped by SARS-CoV-2 infection of the airway epithelial cells. Thus, prominent epigenetic regulators including HDAC2 and BRDs (BRD2, BRD4) interact with viral proteins Nsp5 and E, respectively. Nsp5 antagonizes HDAC2 transport into the nucleus; therefore, affecting HDAC2-induced inflammatory functions and IFN response [18, 45]. Altogether, the hyperinflammatory cytokine and chemokine storm observed in ARDS patients result from epigenetic modifications present in both HCoV infected epithelial cells and immune cells present in their vicinity.

#### **Epigenetic treatments controlling immune hyperactivation**

Epigenetic interventions must be urgently directed against cytokine storm to avoid or reduce ARDS and rising mortality (Fig. 2). Targeted anti-cytokine methodologies have proven efficacious in handling cytokine storm syndrome

[77]. Dexamethasone, an effectual corticosteroid, was shown recently to decrease the cytokine storm syndrome with reduced mortality rates in COVID19 patients [84, 85]. IL-1 inhibitor anakinra and the IL-6 receptor inhibitor tocilizumab proved a remarkable survival benefit in patients experiencing hyperinflammation post-SARS-CoV-2 infection [80, 81]. IFN- $\alpha$  $\beta$  and IFN- $\gamma$  inhibitors mitigate HCoV-induced inflammation; the timing of IFN antagonism therapy must be taken into consideration as it defines the disease outcome. An early IFN response was protective in SARS-CoV-infected mice unlike a delayed IFN signaling. During delayed severe stages of SARS-CoV, IFN- $\alpha$  $\beta$  receptor antagonists prevent inflammatory responses; IFN $\gamma$  neutralization limited IFN- $\alpha$  production [78, 79]. Supplementary, anti-TNF $\alpha$  antibody administration significantly dampened IFN $\gamma$  content [79]. DNA methylation is directed via DNA methylase DNMT3a/b by binding of H3K9 histone methyltransferase G9a to the TNF $\alpha$  promoter which will then render TNF $\alpha$  promoter in a transcriptionally repressive state, resulting in reduced TNF $\alpha$  protein levels. Histone acetylation (H3K9ac, H3K36ac, and H4K5ac) triggers the suppression of IL-8 and TNF $\alpha$  levels which were majorly produced in response to CoV. By means of broad spectrum HDACi, TSA, the production of these proinflammatory mediators was curbed [64, 76].

Resveratrol counteracts hyperinflammation by interfering with NF- $\kappa$ B pathway [51]. It potentiates SIRT1 which directly interacts with p65 via deacetylation on lysine 310 resulting in the inhibition of NF- $\kappa$ B activation. Additionally, inhibiting NF- $\kappa$ B activity via SIRT1-AMPK signaling pathway in the cytoplasm promotes an enhanced anti-inflammatory effect. In fact, NF- $\kappa$ B activation is required for the production of numerous proinflammatory cytokines including TNF- $\alpha$ , IL-1 $\beta$ , IL-6, and proinflammatory chemokines. Besides, resveratrol reduces TNF- $\alpha$ -induced phospho-p38 MAPK expression [86–88].

Baricitinib, a JAK inhibitor as well as an AP2-associated protein kinase 1 (AAK1) inhibitor, was approved for inhibiting IFN- $\alpha$  production in hyperinflammatory cases caused by SARS-CoV-2 [81, 89]. Epigenetic drugs targeting proinflammatory and anti-inflammatory cytokines/chemokines act as a beneficial forecaster of long-term outcome for CoVs infections. The aim is to dampen the major proinflammatory cytokines (IL-6, TNF- $\alpha$ , IL-1 $\beta$ ) and chemokines (IL-8, MCP-1, CCL5) response while enhancing the role of anti-inflammatory cytokines (IL-10 and TGF- $\beta$ ). Altering DNA methylation and histone acetylation states in the IL-6 promoter will impact IL-6 expression [90–92]. Histone acetyltransferase inhibitors (HATi) such as anacardic acid, MG149, and C646 suppress IL-6 levels [60, 61]. Decitabine or 5-aza-2-deoxycytidine (5-azadC), a nucleoside-based DNMT inhibitor, is widely used to inhibit DNA methylation in macrophages; thus, suppressing inflammation [58, 70, 93]. A recent

study suggested that the decrease of suppressor of cytokine signaling 1 (SOCS1) via promoter hypermethylation is strongly associated with overproduction of proinflammatory cytokines (TNF- $\alpha$  and IL-6) illuminating the use of DNMTi [90]. Besides, 5-azadC induced IL-10 marker and TGF- $\beta$  [58, 70, 93]. Belinostat and domatinostat enhanced the expression of TGF- $\beta$  [58]. Moreover, treatment with TSA resulted in increased production of IL-10 [63, 67, 69]. Hence, elevation of IL-10 and TGF- $\beta$  levels might curtail the hyperinflammatory storm observed in COVID-19 patients associated with poor prognosis.

**Combination therapy to fight coronavirus infections including antiviral and epigenetic drugs**

Suitable combination therapies reduce the likelihood of drug resistance, suppress viral replication, lower toxicity levels, and provide synergistic effects (Table 1). Achieving high potency intensities, combinatorial treatments were employed especially in RNA viruses which mutate at higher rate than DNA viruses. However, care must be

taken in order to avoid unwanted contraindications. Although there is no clinically approved antiviral drug or vaccine available to be used against COVID-19, few therapeutic combinations have been evaluated to cope with this viral outbreak. Some patients were clinically recovered after the administration of remdesivir combined with chloroquine (CQ) or IFN- $\beta$  due to the significant blockade of the SARS-CoV-2 replication [89]. In Saudi Arabia, a clinical trial discovered that a combination of lopinavir/ritonavir and IFN- $\beta$ 1b was shown to be effective among MERS-CoV-infected patients [12]. It is also hypothesized that the combination of lopinavir/ritonavir and arbidol will deliver enhanced efficacy against SARS-CoV-2 for a synergistic effect is predictable [16]. A higher potency of antiviral therapy was achieved after the fusion of ribavirin and IFN with immunomodulating agents such as intravenous N-acetylcysteine [94]. Few synergistic combinations resulting from a network-based analysis include sirolimus and dactinomycin, an approved RNA synthesis inhibitor, target HCoV-associated

host protein subnetwork by “complementary exposure” pattern, resulting in potential combination regimens for treatment of HCoV. To successfully inhibit MERS-CoV replication, kinase inhibitors were combined with other host-targeting molecules such as peroxisome proliferator-activated receptor alpha (PPAR- $\alpha$ ) agonists [11]. In a retrospective analysis, ribavirin was tested in combination with corticosteroids, immunoglobulins, and/or antibiotics for SARS-CoV; no efficacy and high fatality rates were shown. Since ribavirin treatment did not improve patient outcome health, Canada stopped permitting the use of ribavirin. Additional studies tested the activity of ribavirin jointly with lopinavir against SARS-CoV. Compared to the control groups, confirmed SARS-CoV cases undergo a milder disease progression with no consequences. In another retrospective analysis, patients were treated with oral ribavirin and SC pegylated IFN- $\alpha$ 2a for 2 weeks. At day 14 after confirmed diagnosis of MERS, survival was increased in the tested group (70%) compared to the control (29%). In an additional case study, an elderly patient who was infected with MERS in Jeddah was treated with oral lopinavir/ritonavir, pegylated IFN, and ribavirin. Viral RNA was detected in feces, serum, and respiratory secretions’ samples after 2 days for initiating the therapy and up to 2 weeks. An ongoing randomized clinical trial in Saudi Arabia is evaluating treatment of MERS patients with IFN- $\beta$ 1b conjointly with lopinavir/ritonavir due to the latter’s high efficacy [4]. Among clinical treatments studied for treating SARS-CoV, combinations of steroid with either alfacon-1, a recombinant consensus IFN- $\alpha$ , or protease inhibitors and ribavirin were found to improve patients’ health [56]. Patients with COVID-19 are being recruited in randomized trials to evaluate the efficacy of favipiravir plus IFN- $\alpha$  and favipiravir plus baloxavir marboxil (an approved influenza inhibitor targeting the cap-dependent endonuclease). The synergism between a pegylated-IFN and a nucleoside compound against COVID-19 is still ambiguous [16]. In spite of drug repurposing and the use of targeted antiviral therapies (CQ, remdesivir, rapamycin, ribavirin), epigenetic drugs such as BRD4 inhibitors, DNMT1 inhibitors, and HDAC inhibitors have been demonstrated to potentially inhibit SARS-CoV-2 [4, 14, 45, 95]. Novel broad spectrum replication inhibitors such as remdesivir or GS-5734 (Gilead Sciences, in phase I clinical trial), and immunomodulators along with direct-acting antiviral agents that are in development could make an efficient amalgamation for treating HCoVs [4]. Knowing that the core treatment for eradicating HCoVs is controlling replication and immune response, offering drug therapies that target both pathways could be the best approach. Some epigenetic therapies have a dual action; resveratrol decreased the expression of NP protein in addition to SIRT-1

activation which counteracts viral replication and hyperinflammation [51]. The anti-viral and anti-inflammatory effects of CQ may play a crucial role in prevention and treatment of COVID-19 as it operated at entry and post-entry phases of SARS-CoV-2 infection [16, 96–98]. Generally, CQ blocks viral infection by elevating endosomal pH necessary for entry, replication, and maturation. For MERS-CoV and SARS-CoV, CQ interfered with cellular proteases and glycosylation of ACE2, respectively [16, 98]. Along with CQ’s antiviral effect, CQ decreases the production of pro-inflammatory indicators and cytokines reducing cytokine storm destruction [96, 97]. Merging antiviral drugs with epigenetic therapies targeting hyperinflammation is considered as an alternative. Antivirals (remdesivir, ribavirin, favipiravir, and galidesivir) could be combined with DNMTi (decitabine, azacitidine) or HDACi (vorinostat, belinostat, panobinostat, TSA). However, further preclinical experiments and clinical trials are required to validate the clinical benefits of these combined candidates. Epidemiological studies showed that the majority of severe SARS-CoV-2 cases were elderly patients with comorbid conditions whereas children cases have been rarely reported [3, 54] suggesting the use of anti-aging drugs targeting epigenetics (resveratrol), other anti-aging drugs (CQ, rapamycin, and doxycycline) and senolytics (azithromycin and quercetin) which could decrease substantial morbidity and mortality [99, 100]. Several anti-aging therapeutics exists as FDA-approved drugs with acceptable safety profile proposing their use in COVID-19 prevention [99].

### Conclusion and perspectives

Providing more research to generate infection control therapeutic interventions is a major challenge. The three coronavirus global outbreaks emphasized the exigent need for curtailing CoVs infections despite the presence of many therapeutic options including epigenetic therapy, antivirals, and repurposing drugs. Cationic amphiphilic drugs, analogs of previously developed drugs, antibody therapy, structure-based drug design, and combination therapies are considered as researchers’ key for further novel antiviral drug development [4, 89]. Safe and effective coronavirus vaccine is the ultimate weapon for reducing morbidity and mortality rates. Coronavirus S protein is considered a strategic board for vaccines [89, 101]. Although several vaccination strategies are being tested against CoVs, these studies are still in progress [14, 89]. Live attenuated and deactivated virus, viral vectors, recombinant DNA, subunit, and protein vaccines are considered as the main approaches [14]. Additional clinical and laboratory evidences must be investigated to validate the use of vaccines proposed by several academic institutions [11, 14, 17, 89, 101]. A recent study specified the clinical benefits of the

microneedle array (MNA) delivered recombinant protein subunit vaccines as a favorable immunization strategy against SARS-CoV, MERS-CoV, and SARS-CoV-2 [101]. In closing, research efforts must be deepened through all outbreak stages to end coronavirus pandemic and epigenetic-targeted therapy could be a major asset in restricting severe HCoV infections.

Springer Nature remains neutral with regard to jurisdictional claims in published maps and institutional affiliations.

#### Ready to submit your research? Choose BMC and benefit from:

- fast, convenient online submission
- thorough peer review by experienced researchers in your field
- rapid publication on acceptance
- support for research data, including large and complex data types
- gold Open Access which fosters wider collaboration and increased citations
- maximum visibility for your research: over 100M website views per year

At BMC, research is always in progress.

## 11.2 Publication N°2

Haidar Ahmad S, Al Moussawi F, **El Baba R**, Nehme Z, Pasquereau S, Kumar A, et al. Identification of UL69 Gene and Protein in Cytomegalovirus-Transformed Human Mammary Epithelial Cells. *Front Oncol* 2021;11:627866. <https://doi.org/10.3389/fonc.2021.627866>.

A growing body of evidence suggests that human cytomegalovirus (HCMV) is involved in cancer development, particularly in breast tumors. HCMV-infected human mammary epithelial cells (HMECs) give rise to rapidly proliferating, spheroid-shaped cells called CTH cells, indicating HCMV's contribution to oncogenesis. This study focused on the UL69 gene in HCMV, which was detected in CTH cells and breast cancer biopsies. In our experiments, ganciclovir treatment reduced UL69 gene presence and cell proliferation, while UL69 knockdown using siRNA affected HCMV replication and CTH cell growth. These findings highlight the direct role of HCMV in breast tumor development, particularly through the UL69 gene.

doi: 10.3389/fonc.2021.627866

A growing body of evidence addressing the involvement of human cytomegalovirus (HCMV) in malignancies had directed attention to the oncomodulation paradigm. HCMV-DB infected human mammary epithelial cells (HMECs) in culture showed the emergence of clusters of rapidly proliferating, spheroid-shaped transformed cells named CTH (CMV-Transformed HMECs) cells. CTH cells assessment suggests a direct contribution of HCMV to oncogenesis, from key latent and lytic genes activating oncogenic pathways to fueling tumor evolution. We hypothesized that the presence of HCMV genome in CTH cells is of pivotal importance for determining its oncogenic potential. We previously reported the detection of a long non-coding (lnc) *RNA4.9* gene in CTH cells. Therefore, we assessed here the presence of *UL69* gene, located nearby and downstream of the *lncRNA4.9* gene, in CTH cells. The HCMV *UL69* gene in CTH cells was detected using polymerase chain reaction (PCR) and sequencing of *UL69* gene was performed using Sanger method. The corresponding amino acid sequence was then blasted against the *UL69* sequence derived from HCMV-DB genome using NCBI Protein BLAST tool. A 99% identity was present between the nucleotide sequence present in CTH cells and HCMV-DB genome. *UL69* transcript was detected in RNA extracts of CTH cells, using a reverse transcription polymerase chain reaction (RT-PCR) assay, and pUL69 protein was identified in CTH lysates using western blotting. Ganciclovir-treated CTH cells showed a decrease in *UL69* gene detection and cellular proliferation. In CTH cells, the knockdown of *UL69* with siRNA was assessed by RT-qPCR and western blot to reveal the impact of pUL69 on HCMV replication and CTH cell proliferation. Finally, *UL69* gene was detected in breast cancer biopsies. Our results indicate a close link between the *UL69* gene detected in the HCMV-DB isolate used to infect HMECs, and the *UL69* gene present in transformed CTH cells and tumor biopsies, further highlighting a direct role for HCMV in breast tumor development.

**Keywords:** cytomegalovirus - HCMV, UL69, CTH cells, oncogenesis, latency

## INTRODUCTION

Human cytomegalovirus (HCMV) is a large double-stranded DNA virus of the Betaherpesvirinae subfamily, with a genome length of approximately 230 kbp (1). HCMV genome encodes for more than 700 short open reading frames (sORFs) and is composed of two unique regions, each flanked by inverted repeats (2, 3). During the lytic cycle, active viral genome replication results in the release of new viral particles, in contrast to the latency phase, during which a limited number of viral gene products are expressed. Latency is established depending on cell type-specified mechanisms related to transcriptional silencing unlike the reactivation phase triggered by diverse stimuli, for instance infection, inflammation, and injury (4). Studies have shown that HCMV activates pro-oncogenic pathways in infected cells, resulting in a modified cellular phenotype that favors transformation (5, 6). Indeed, HCMV gained a considerable attention in cancer due to many factors that could underlie its potential oncogenic role. The latter includes supporting proliferative signals, evading growth suppression while stimulating metastasis and invasion, permitting replicative immortality and angiogenesis, resisting cell death, escaping immune destruction, as well as inducing genome variability including mutations, and tumor stimulating inflammation (7, 8).

We previously observed that the infection with the clinical strain HCMV-DB resulted in the transformation of HMECs in culture, with the appearance of clusters of spheroid cells that contributed to the formation of CMV-transformed HMECs or CTH cells (6). When xenografted in NOD SCID gamma (NSG) mice, CTH cells underwent unchecked proliferation and gave rise to tumors (6). To determine the potential causal role of HCMV in the transformation of CTH cells, it is critical to detect the presence of HCMV genome in those transformed cells. Since the two oncogenic herpesviruses discovered so far, Epstein-Barr virus (EBV) and Kaposi's sarcoma-associated herpesvirus (KSHV) exploit both latency and low lytic viral replication to fuel the oncogenic process (9–11), we decided to study HCMV genes and proteins expressed in CTH cells, even at low levels. In this context, studies have shown that few HCMV genes such as *UL123* and *UL122* immediate early genes, *UL7*, *UL111A*, *UL112*, *US28*, *US33*, *UL135*, *UL136*, and *lncRNA4.9* could be responsible for the tumorigenic phenotype observed in some human malignancies (12). Previously, we detected the presence of a 126 bp amplicon corresponding to the sequence of *lncRNA4.9* gene (nt95592- nt95717) of HCMV-DB strain in CTH cells (6).

**Abbreviations:** A, adenine; C, cytosine; CDK19, cyclin dependent kinase 19; CTH cells, CMV Transformed HMECs; EBV, Epstein-Barr virus; G, guanine; HCMV, human cytomegalovirus; HMECs, human mammary epithelial cells; IFN, interferon; IHD, ICP27 homology domain; KSHV, Kaposi's sarcoma-associated herpesvirus; *lncRNA4.9*, long non-coding RNA4.9; MMP-10, matrix metalloproteinase-10; MSA, multi-sequences alignments; NTC, no template control; PCR, polymerase chain reaction; RT, reverse transcriptase; RT-PCR, reverse transcription polymerase chain reaction; SIMs, SUMO-interacting sequences; sORFs, short open reading frames; STING, stimulator of interferon genes; SUMOs, small ubiquitin-like modifiers; T, thymine; WES, whole exome sequencing.

Since the previously detected *lncRNA4.9* is a non-coding sequence (6), we decided to further assess the presence of the nearby coding HCMV gene *UL69*, which might be a part of the transformation machinery.

Herein, we detected the presence of *UL69* gene in CTH cells using extensive PCR analysis and sequencing. Using phylogenetic analysis, we confirmed that the detected *UL69* gene in CTH cells matches the *UL69* gene sequence of HCMV-DB strain originally used to infect and transform HMECs into CTH cells by 99%. At the proteomic level, the pUL69 sequence present in CTH cells differs from the HCMV-DB original pUL69 only in two amino acid point mutations. At the transcriptome level, we detected the transcript of *UL69* and pUL69 in CTH cells. Besides, in agreement with a coding role for *UL69* HCMV gene, we detected the expression of the pUL69 in CTH cells *in vitro*. Upon *UL69* knockdown using siRNA, we observed a decrease in viral replication and CTH proliferation. *In vivo*, we identified *UL69* gene with a high frequency in biopsies of breast cancer patients.

## MATERIALS AND METHODS

### Isolation and Culture of CTH Cells

Several clusters of spheroid-cells were observed in HCMV-DB infected HMECs around day 20 post-infection in some of the cultures. These clusters were gently detached and the floating detached cells named CTH cells were cultured in HMEC Ready medium (Cat#12752010, Gibco, Grand Island, NY) for numerous passages, currently >150 passages (6). CTH cells used in this study were cultivated for approximately 410 days. HMECs cultures were infected with HCMV-DB at MOI of 1 as previously reported (13). An inverted light microscope (Olympus, Japan) was used to count cells in CTH cultures.

### Detection of the *UL69* Gene in CTH Cells Using PCR and qPCR Assay

Total DNA derived from uninfected HMECs, HCMV-DB infected HMECs, CTH, and MRC5 cells was extracted using a DNA extraction Kit (EZNA Blood DNA Kit, Omega BIO-TEK, Norcross, GA, USA). The presence of the HCMV sequence spanning the *UL69* gene was determined by qualitative PCR assay. The list of primer sets used to screen for the presence of *UL69* from HCMV-DB genome in CTH cells is described in **Supplementary Table 1**. Primer sets were provided by Eurogentec (Seraing, Belgium). Several Taq polymerases were used depending on the size and GC percent content of the amplified fragment. Dream Taq polymerase, KAPA hot start Taq polymerase, and KAPA fast Taq polymerase were ordered from ThermoFisher (EP0701) and Sigma-Aldrich (KK1512 and KK4601) respectively. HCMV-DB DNA and lysates of HCMV-DB infected HMECs were used as positive controls. As negative controls, both uninfected HMECs and uninfected MRC5 cells were tested in parallel. Amplified products were electrophoresed in 2% agarose gel stained with Sybr green I nucleic acid stain. As an equal loading control,  $\beta$ -globin gene was amplified (sense: 5'-TCCCCTCCTACCCTACTTTCTA-3'; antisense: 5'TGCCTGGACTAATCTGCAAGAG-3'). Using real-time qPCR assay, *UL69* load was

measured in ganciclovir-treated (20  $\mu$ M for 4 days) and untreated CTH cultures in parallel with the cell counting.

### Sequencing of the *UL69* Gene Present in CTH Cells

Fragments amplified by PCR were sequenced using the Sanger method (Genoscreen, Lille, France; GATC, Köln, Germany). PCR products were sent either directly after amplification or after gel cutting to harvest the band of the expected size (in case of several bands). **Supplementary Table 1** includes the primers used for sequencing. PCR amplifications and Sanger's sequencing were repeated twice. The obtained sequences were prepared using the BIOEDIT software (14). Sequences were compared against the sequence of the HCMV-DB strain (accession number KT959235) (13) using NCBI nucleotide blast tool (<https://blast.ncbi.nlm.nih.gov/BlastAlign.cgi>).

### Detection of the *UL69* Transcript by RT-PCR

RNA was extracted from CTH cells using RNA extraction kit (EZNA Total RNA Kit I, Omega BIO-TEK). Following DNase I treatment for 30 minutes (ThermoFisher), cDNA was synthesized from extracted RNA using Superscript IV First-strand synthesis kit (ThermoFisher) as per manufacturer instructions. cDNA was then used as a template for qualitative PCR amplification using *UL69* primers and Dream Taq polymerase (ThermoFisher) as described above. Lysates of HCMV-DB infected HMECs were used as positive controls. The amplified product was electrophoresed in 2% agarose gel stained with Sybr green I nucleic acid stain.

*UL69* knockdown with siRNA performed on CTH cells was assessed by the quantification of *UL69* RNA transcripts. Following RNA extraction and DNase I treatment as described above, cDNA synthesis was performed. Real-time qPCR detection of *UL69* was performed using KAPA SYBR FAST Master Mix (KAPA BIOSYSTEMS, KK4601) and *UL69* gene primers (sense: 5'-GGGATGTCGATGACTCCCTTC-3'; antisense: 5'-GTCCGCTATTGGATCTCACCGT-3'), according to the manufacturers' instructions. Real-time qPCR reactions were activated at 95°C for 10 minutes and then 50 cycles (15 s at 95°C and 1 min at 60°C) were conducted using a Stratagene Mx3005P thermocycler (Agilent Technology, Santa Clara, CA, USA). The results were recorded and analyzed using MxPro qPCR software.

### Western Blotting

Western blot was performed as described previously (13). Both controls and CTH cells were lysed and proteins were separated by electrophoresis on SDS-PAGE gel. Proteins were transferred to a nitrocellulose membrane. After blocking in 5% milk, the membrane was incubated overnight with 1  $\mu$ g/ml anti-pUL69 polyclonal antibody (kindly provided by Dr. Stamminger, Erlangen University, Germany). Blots were developed with the ECL detection kit (Amersham Biosciences, Piscataway, NJ).

The siRNA-mediated knockdown of *UL69* was assessed by western blot. Cellular extracts of transfected CTH cells with scramble siRNA and *UL69* siRNA were prepared at day 1 post-transfection. In addition, cellular extracts of MRC5 infected with

HCMV-DB and transfected with scramble siRNA and *UL69* siRNA were prepared 24 hours post-transfection.  $\beta$ -actin was used as a control to normalize sample loading.

### Flow Cytometry Analysis

The proliferation of CTH cells was assessed using the measurement of Ki67 antigen expression by intracellular flow cytometry as described previously (15).

### Soft Agar Assay

Colony formation in soft agar seeded with ganciclovir-treated (20  $\mu$ M for 4 days) and untreated CTH cells was assayed. Ganciclovir-treated and untreated CTH cells were incubated for 14 days in the semisolid agar medium. Colonies were observed under an Olympus microscope as previously reported (6).

### Transfection Assay

A total of  $0.25 \times 10^6$  cells (HMECs and CTH cells) were transfected with 1-2  $\mu$ g total plasmid DNA, namely plasmids pUL69, empty pcDNA3.1 (16) and pGFP (17) using JetPEI transfection reagent (Polyplus Transfection, Illkirch, France) as per manufacturers' protocol. pGFP-positive cells were gated and Ki67Ag expression was measured 24 hours post-transfection in pGFP-positive cells using flow cytometry.

### RNA Interference

HCMV-DB infected MRC5 and CTH cells were transfected with scramble siRNA or *UL69* siRNA (sense:ACUCAGCCGUUUGAUCGAATT; anti-sense:UUCGAUCAAAACGGCU GAGUTG) (Life Technologies, Carlsbad, CA, USA) using Lipofectamine RNAiMAX (Life Technologies) according to the manufacturer's protocol. Transfection efficiency was monitored 24 hours post-transfection for HCMV-DB infected MRC5 cells by western blot and for CTH cells by RT-qPCR and western blot as described above.

### Determination of Amino Acid Sequences

Amino acid sequence derived from *UL69* gene present in CTH cells was obtained using the MBS translator software (<http://insilico.ehu.es/translate/>) (18). The *UL69* amino acid sequence existing in CTH cells was blasted against the pUL69 sequences derived from the HCMV-DB genome (KT959235) (13) using NCBI protein blast tool (<https://blast.ncbi.nlm.nih.gov/Blast.cgi>).

### Phylogenetic Analysis

Multi-sequences alignments (MSA) were performed using CLUSTAL W. Phylogenetic tree was obtained using the neighbor-joining method and MEGA7 software (<http://www.megasoftware.net/>) as previously described (6).

### Measurement of HCMV Growth

Viral replication was assessed by the quantification of HCMV load following DNA extraction (EZNA Blood DNA Kit, D3392-02, Omega BIO-TEK) by real-time qPCR detection using KAPA SYBR FAST Master Mix (KAPA BIOSYSTEMS, KK4601) and

primers specific for the IE1 gene (sense: 5'-CGACGTTC CTGCAGACTATG-3'; antisense: 5'-TCCTCGGTCACCTGT TCAA-3') according to the manufacturer's protocol. Real-time qPCR reactions were activated at 95°C for 10 minutes, followed by 50 cycles (15 seconds at 95°C and 1 minute at 60°C) using a Stratagene Mx3005P thermocycler (Agilent). Results were collected and analyzed using MxPro qPCR software.

### Detection of UL69 DNA in Breast Tumor Tissue

All patients who were admitted to Besançon University Hospital (Besançon, France) gave their written informed consent to participate in the study according to the Helsinki declaration. The study was approved by the local ethics committees of Besançon University Hospital (Besançon, France) and the French Research Ministry (AC-2015-2496, CNIL n°1173545, NF-S-96900 n°F2015). Genomic DNA isolated from biopsies of breast cancer patients (n=30) was provided by the regional tumor bank (BB-0033-00024 Tumorthèque Régionale de Franche-Comté). Paired adjacent healthy tissue (n=29) was utilized in the study. 29 paired adjacent healthy samples match 29 tumor samples, but only one of the tumor samples lacks the corresponding healthy tissue. Breast tissues from non-tumor breast disease (n=4) were used as control. For histological grading of breast cancer biopsies, the Elston-Ellis grade was used with the three factors of grading: tubule formation, nuclear pleomorphism, and mitotic count. Each factor is given a score of 1 to 3 (1 being the best; 3 the worst) and the scores of all the three factors are then added up to give a total of 3 to 9 points indicating the tumor grade. Tumor grade is allocated on the following basis: 3 to 5 points: grade I (well-differentiated); 6 to 7 points: grade II (moderately differentiated); 8 to 9 points: grade III

(poorly differentiated) (19). The presence of HCMV was determined by quantitative PCR using *UL69* primers (sense: 5'-GGGATGTCGATGACTCCCTC-3'; antisense: 5'-GTCGCTATTGGATCTCACCGT-3') as reported previously (6).

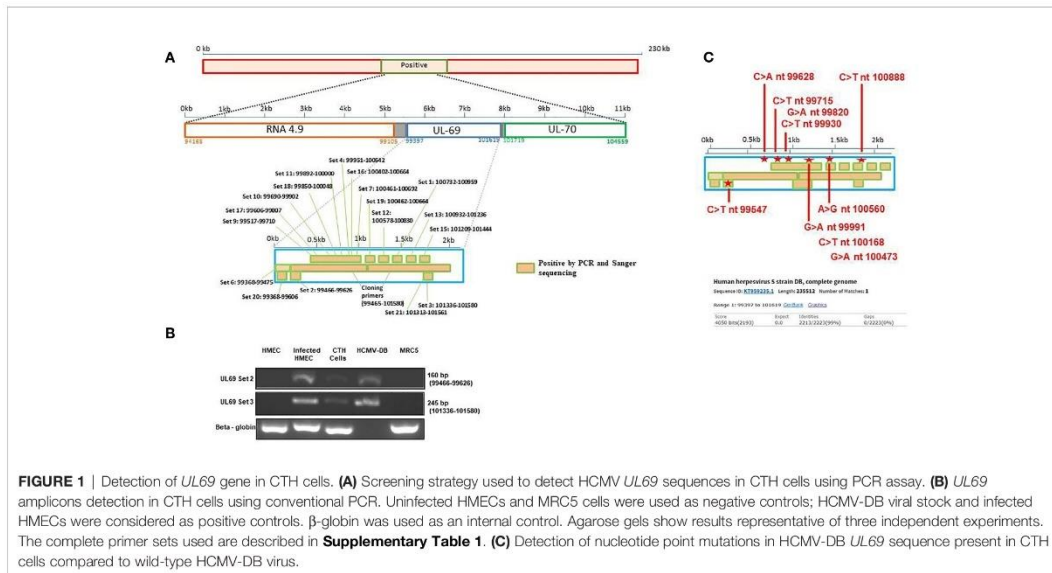

### Statistical Analysis

The reported values represent the mean and SD of independent experiments. Statistical analysis was performed using Mann Whitney U test and differences were considered significant at a value of *p*-value < 0.05. Microsoft Excel was used for plot construction. Correlation analysis was done using Spearman test (Statistical software SPSS 23). Based on Spearman's rank correlation coefficient ( $\rho$ ), all bivariate correlation analyses express the strength of association between two variables where  $r = +1$  (positive correlation) and the value  $r = -1$  (negative correlation). Results were interpreted according to the degree of association as strong (0.7–1), moderate (0.5–0.7), or low (0.3–0.5), taking significant correlation (*p*-value < 0.05) values into consideration.

## RESULTS

### Presence of HCMV-DB *UL69* Gene Signature in CTH Cells

Since we previously identified *hncRNA4.9* sequences in CTH cells (7), we screened for the presence of the downstream and nearby *UL69* gene using primers spanning the complete gene region (Figure 1A, Supplementary Table 1). Using PCR assay, we first detected two HCMV-DB sequences in CTH cells corresponding to 160 bp and 245 bp *UL69* gene amplicons (Figure 1B), indicating that the complete *UL69* gene could be present in CTH cells. After

demonstrating the presence of *UL69* genomic sequences in CTH cells, we used several primers sets to span the complete *UL69* gene (Table 1). Overall, we were able to detect the existence of a set of viral sequences in CTH cells that corresponds to the complete *UL69* gene (nt99397- nt101619) (Figure 1B, Table 1). *UL69* amplicons of the same size were also amplified in positive controls, including HMECs infected acutely with HCMV-DB and HCMV-DB viral stock (Figure 1B), whereas no HCMV sequences were detected in uninfected HMECs and uninfected MRC5 cells used as negative controls (Figure 1B).

### Detection of Nucleotide Point Mutations in *UL69* Gene Present in CTH Cells Compared to the Original HCMV-DB Strain

To definitively confirm the presence of *UL69* gene in CTH cells, obtained *UL69* amplicons covering the complete gene were sequenced using the Sanger's method. *UL69* sequences present in CTH cells were then compared to the HCMV-DB genome sequence (KT959235) by using BLAST analysis. We detected ten nucleotide point mutations in the *UL69* sequence obtained from CTH cells compared to the parental HCMV-DB sequence (Figure 1C, Table 2, Supplementary Figure 1). Thoroughly, a 99% identity was established between the *UL69* nucleotide sequence present in CTH cells and HCMV-DB genome (Figure 1C, Supplementary Figure 1).

### Detection of the *UL69* Transcript and Protein in CTH Cells

Following the detection of *UL69* sequence in CTH cells, we subsequently assessed the presence of *UL69* transcript and pUL69 protein in CTH cells. Using RT-PCR assay, we detected *UL69* transcript in RNA extracts of CTH cells (Figure 2A). We next analyzed the presence of pUL69 protein in CTH cells using western blotting. MRC5 cells infected with HCMV-DB were used as a positive control (Figure 2B). Despite its low levels, pUL69

protein was detected in CTH cells lysates at the expected size (82 kDa) (Figure 2B, red arrow). Intriguingly, one additional band of approximately 60 kDa was observed in CTH lysates compared to HCMV-infected MRC5 cells (Figure 2B, unidentified band). Amino acid sequence derived from *UL69* gene present in CTH cells was obtained using the MBS translator software (<http://insilico.ehu.es/translate/>) (18). *UL69* amino acid sequence existing in CTH cells was blasted against pUL69 sequence derived from the HCMV-DB genome (KT959235) (13) using NCBI Protein BLAST tool (<https://blast.ncbi.nlm.nih.gov/Blast.cgi>). Two residue mutations were detected in pUL69 protein in CTH cells compared to the original HCMV-DB strain. The first mutation is at position 564, where the amino acid threonine (T) in HCMV-DB is changed to alanine (A) in CTH cells. The second one is at position 664, where the amino acid aspartic acid (D) is replaced by glutamic acid (E) (Figure 2C, Table 2).

### Phylogenetic Analysis of *UL69* Gene and pUL69 Protein Present in CTH Cells

*UL69* gene present in CTH cells was compared to its counterpart present in HCMV-DB genome, in parallel to comparison with ten other clinical and laboratory-adapted HCMV strains described previously (Figure 3) (5). We observed that *UL69* genomic sequence in CTH cells was mostly analogous to the *UL69* gene of TB40/E clinical strain than to that of the parental HCMV-DB strain (Figure 3A), indicating a shift of the *UL69* genomic sequence from HCMV-DB strain toward TB40/E strain. Similarly, at the protein level, we observed a shift from pUL69 protein of HCMV-DB strain toward TB40/E strain in CTH cells (Figure 3B). This analysis was performed over three independent experiments.

### Ganciclovir Treatment of CTH Cells Decreases Both *UL69* Gene Detection and Cell Proliferation

Since *UL69* and the previously described *lncRNA4.9* genes are detected in CTH cells, we assessed the presence of *UL69* gene in culture supernatants of CTH cells. We detected a very low viral load (around 2 log copies/ml) in culture supernatants of CTH cells, indicating the incidence of a relatively slow viral lytic cycle rate. Upon ganciclovir treatment, a 95% decrease in the viral load was detected in CTH cultures as measured by *UL69* quantification, further indicating that HCMV is replicating in CTH cells. Interestingly, parallel to the *UL69* decrease, ganciclovir treatment diminished the CTH cell count in culture by 41%, the CTH cell proliferation by 54%, and the size of the colonies observed in soft agar (Figures 4A–D).

### pUL69 Favors HCMV Replication and CTH Cell Proliferation

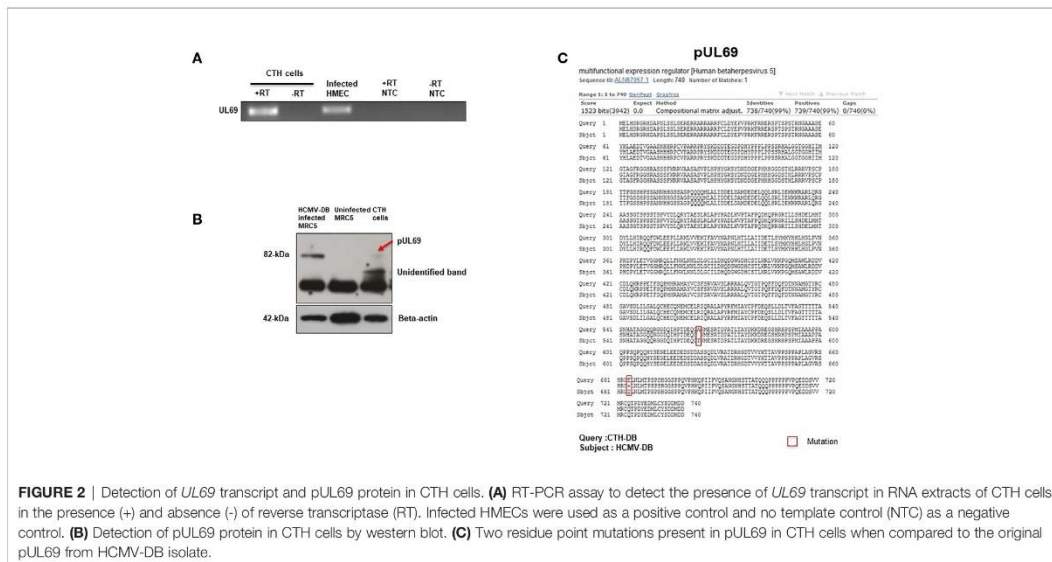

To further clarify the role of *UL69* protein in CTH cells, we treated CTH cells with *UL69* siRNA and a scramble control. Knockdown of *UL69* transcript and protein in CTH cells was monitored by RT-qPCR assay and western blot, respectively (Figures 5A, B). In addition, knockdown of *UL69* protein was assessed in MRC5 cells acutely infected with HCMV-DB (Supplementary Figure 2A) in parallel with decreased HCMV

**TABLE 1** | Amplicon positions and sizes of the *UL69* HCMV-DB gene screened in CTH cells using qualitative and/or quantitative PCR.

Gene	Amplicon position	Amplicon size (bp)	PCR amplification result in CTH cells
<i>UL69</i>	99368-99475	108	Positive
	99368-99606	258	Positive
	99465-101580	2115	Positive
	99466-99625	160	Positive
	99517-99710	194	Positive
	99606-99807	202	Positive

	101336-101580	245	Positive

**TABLE 2** | Detection of nucleotide point mutations in the *UL69* gene present in CTH cells compared to the HCMV-DB.

Mutation position	Nucleotide change between HCMV-DB and CTH cells	Codon change between HCMV-DB and CTH cells	Transcribed Codon change between HCMV-DB and CTH cells	Amino acid in HCMV-DB and CTH cells
99547	T → C	TTG → CTG	CAA → CAG	Glutamine
99628	A → C	ATC → CTC	GAU → GAG	Aspartic acid → Glutamic acid
99715	T → C	TCG → CCG	CGA → CGG	Arginine
99820	A → G	AGC → GGC	GCU → GCC	Alanine
99930	T → C	TGT → TGC	ACA → GCU	Threonine → Alanine
99991	A → G	ATG → GTG	CAU → CAC	Histidine
100168	T → C	TGA → CGA	UCA → UCG	Serine
100473	A → G	CAA → CAG	UUG → CUG	Leucine
100560	G → A	CAG → CAA	CUG → UUG	Leucine
100888	T → C	TGA → CGA	UCA → UCG	Serine

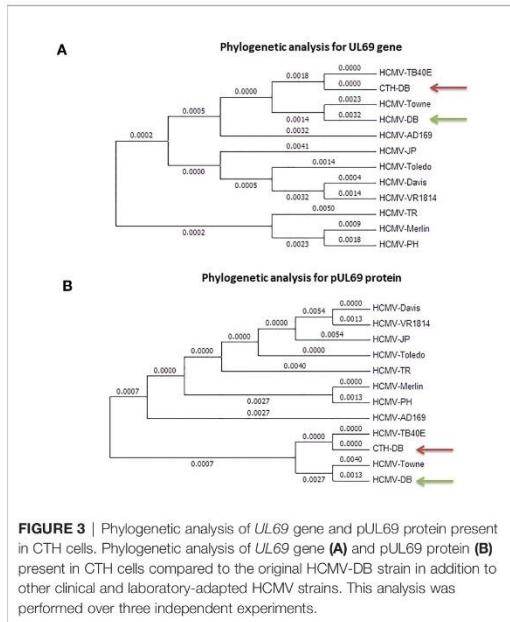

replication in culture (Supplementary Figure 2B). Knockdown of *UL69* decreased both HCMV growth in CTH cell culture (Figure 5C) and CTH cell proliferation (Figure 5D). In addition, after overexpressing pUL69 in HMECs and CTH cells, we observed an increase in cell proliferation at 24 hours post-transfection using Ki67Ag detection by flow cytometry (Figure 5E). Altogether, our data indicate that *UL69* favors both HCMV replication and cell proliferation in CTH culture.

### Detection of *UL69* DNA Within Breast Cancer Biopsies

To further demonstrate the pathophysiological relevance of the CTH cell model *in vivo*, we assessed the expression of the *UL69* gene in the genomic DNA obtained from human breast cancer biopsies and paired adjacent healthy tissue. Breast cancer biopsies were classified into luminal and basal-like biopsies based on the IHC analysis of a pathologist. Breast tissue from patients with non-tumor breast disease was used as control.

Using quantitative PCR, *UL69* gene was detected in 43.33% (n=13/30) and 75.85% (n=22/29) of biopsies from breast tumor and paired adjacent healthy breast tissue (Figure 6A) (*p*-value=0.01). In addition, *UL69* gene was detected in 53.33% (n=8/15) and 33.33% (n=5/15) of biopsies from luminal and basal-like breast cancer, respectively (Figure 6A). In breast tissue taken from patients with non-tumor breast disease, we detected the *UL69* gene in 50% of the cases in agreement with approximately 40%-50% of the French healthy adults harboring the virus (20) with a Ct value of 44.35. Among HCMV-positive (*UL69* gene positive) biopsies, we did not find significant differences in the viral load between paired healthy breast tissue (Ct=44.24), tumor breast tissue (Ct=44.01), luminal breast biopsies (Ct=43.16), and basal-like breast biopsies (Ct=45.38) as measured by quantitative PCR (*UL69* Ct value) (Figure 6B). In tumor biopsies, a significant positive correlation was detected between *UL69* Ct value and tubule formation ( $\rho=0.53$ , *p*-value=0.038). In luminal breast cancer biopsies, a

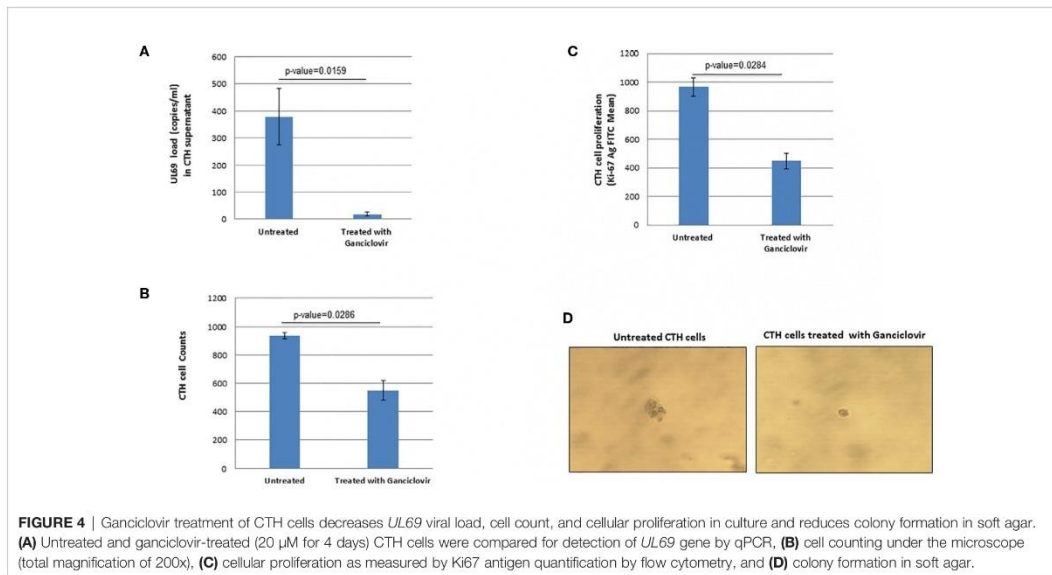

significant positive correlation was also found between *UL69* Ct value and tubule formation ( $\rho=0.62$ ,  $p$ -value=0.05). In addition, in basal-like breast cancer biopsies a significant negative correlation was observed between *UL69* Ct value and nuclear pleomorphism ( $\rho=-0.89$ ,  $p$ -value=0.05) (Table 3).

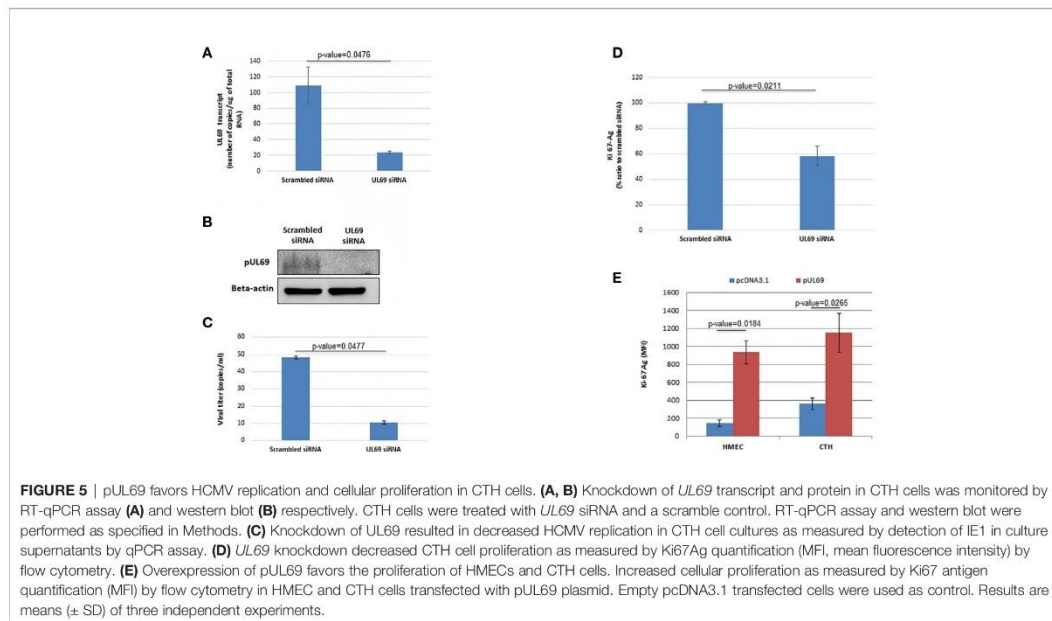

## DISCUSSION

Previously, we reported the transformation of HMECs infected with the HCMV-DB strain, namely the CTH cells (6). To substantiate the causative role of HCMV-DB in HMECs transformation, it is imperative to demonstrate the presence of coding HCMV-DB genes in CTH cells. One short DNA sequence related to the viral *lncRNA4.9* was previously detected in CTH cells. In the present study, we assessed the presence of *UL69* gene located downstream and nearby the *lncRNA4.9*. Upon sequencing the *UL69* gene present in CTH cells, we detected ten nucleotide point mutations that resulted in two amino acid point mutations in pUL69 in comparison with HCMV-DB genome. Remarkably, pUL69 protein, along with its transcript, were detected in CTH cells. Moreover, *UL69* gene was detected in breast cancer biopsies. Overall, our data denote the occurrence of the coding *UL69* gene in CTH cells, with potential pathophysiological relevance in breast cancer.

Earlier, we aimed to determine HCMV-DB signature in CTH cells by whole exome sequencing (WES) adopting Sureselect target enrichment method (21). Using WES, we detected limited sequences of HCMV-DB genomic DNA in the CTH cells genome, where the observed signals were close to the “background noise”. Among those weak WES signals in CTH cells, we noticed some hits corresponding to *lncRNA4.9* sequence of HCMV-DB. This was further confirmed by both qualitative and quantitative PCR that amplified a 126 bp fragment of *lncRNA4.9* originating from HCMV-DB, as confirmed by Sanger’s sequencing (6).

In the present study, *UL69* gene, its corresponding transcript, and pUL69 protein were detected in CTH cells confirming the availability of the *UL69* gene. The *UL69* gene covers a genomic region of 2.2 kb and encodes for 744 amino acids protein (pUL69) (22). pUL69 is a multifunctional regulatory protein belonging to

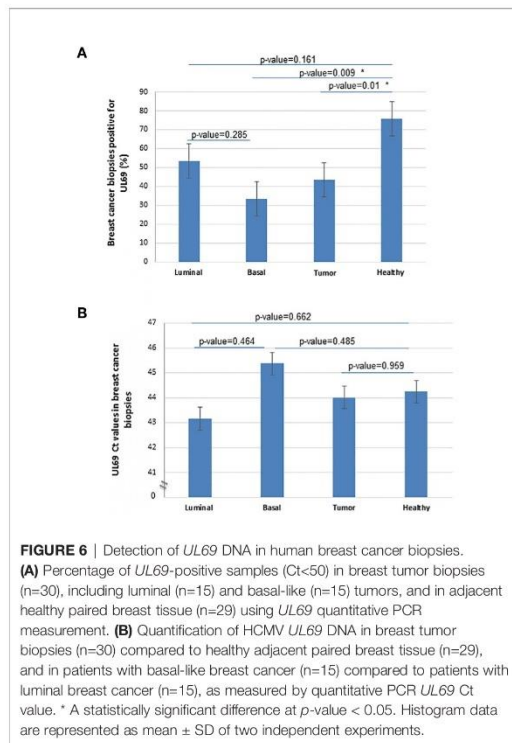

the ICP27 herpesvirus family (23) which contains the ICP27 homology domain (IHD) (24). pUL69 could participate in the transformation of CTH cells *via* two distinct mechanisms: low viral replication levels in parallel to viral latency as already reported for the two oncoviruses (EBV and KSHV), and/or through a direct oncogenic potential of the viral protein (9–11, 25). Those two mechanisms might not be exclusive to each other. In agreement with low levels of viral replication in sustained CTH transformation by HCMV, we observed decreased levels of *UL69* gene in CTH cells treated with ganciclovir. In parallel, this was accompanied by a decrease in CTH cell count in culture, indicating reduced CTH cell proliferation, in addition to a lower number of colony formation in soft agar. Although we cannot exclude the role of other viral proteins in the maintenance of the CTH cell transformation throughout a prolonged cell culture, *UL69* gene and pUL69 might contribute to the exquisite balance between low viral replication and the transformation process. Thus, comparable to EBV and KSHV, HCMV low replication level could fuel oncogenesis, where pUL69 could be part of this process since it targets several stages of the lytic viral cycle such as transcription, mRNA nuclear export, and translation. Indeed, pUL69 is involved in gene transcription and binds *via* its IHD domain to the cellular transcriptional elongation factor SPT6 which favors chromatin remodeling. Upon knocking-down SPT6, an approximately 90% inhibition of the wild-type replication was detected, thus highlighting the significance of SPT6-*UL69* binding in HCMV replication (24, 26, 27). Besides, pUL69 possesses binding motifs for UAP56/URH49 known as cellular mRNA adaptor proteins (28). pUL69 binding to the cellular helicase UAP56 has a role in transcriptional elongation

and also promotes the mRNA nuclear export (16, 29). Additionally, pUL69 contains nuclear export and localization sequences that play a vital role in facilitating the shuttle between the nucleus and the cytoplasm (24). Finally, to modulate translation in HCMV-infected cells, pUL69 interacts with part of the cap-binding complex, eIF4A1, and poly (A) binding protein (30). The detection of low levels of pUL69 protein and low viral replication rate in CTH cells are in line with the previously described constrained viral replication in sustained long term cultures of cancerous cell lines infected acutely with HCMV (31, 32). In fact, it has been shown that persistent HCMV infection of tumor cells may lead to the selection of novel virus variants characterized by changes in the coding sequences for virus regulatory proteins that have lost their ability to induce cell cycle arrest. Thus, persistent HCMV infection of tumor cells results in the development of mutant viral variants, that grow slowly and yield lower amounts of progeny virus compared to the wild-type viral strains originally used for infection (31, 33).

Based on *UL69* knockdown (Figures 5A–D) and overexpression (Figure 5E) experiments, we observed that *UL69* favors both HCMV replication and cell proliferation in CTH cultures. Enhanced cell proliferation could be involved in the sustained growth of CTH cells in culture. In contrast to our data in CTH cells, a pUL69-mediated cell cycle block in G1/S phase has been reported previously in acutely HCMV-infected MRC5 cells (34, 35). The difference in the cell type used (fibroblast versus epithelial cells) and in acute (MRC5 cells) versus chronic (CTH cells) infection could explain the observed discrepancies. In addition, cells with disrupted cell cycle tend to control mechanisms in a similar manner to tumor cells; the function of virus regulatory proteins may depend

on the internal landscape of tumor cells including p53 and Rb expression/mutation (36). For example, HCMV IE2 protein induces a G1/S block in human cells with wild-type pRb, but not in the human Rb-deficient osteosarcoma cell line Saos-2. Similarly, sustained HCMV infection did not induce cell cycle arrest in T89G glioblastoma cells with disrupted p53 signaling, but virus antigen-positive cells continued to divide (37). Interestingly, we previously reported both a functional defect of p53 and Rb downregulation in CTH cells infected with HCMV-DB (6). These findings indicate that the effects of HCMV on cell cycle and cell proliferation may depend on both the landscape of the internal cellular environment (e.g. p53, Rb) and the properties of virus regulatory proteins such as pUL69 (38). Although we did not yet decipher the molecular

mechanism(s) involved in HCMV transformation and the role played by pUL69 (alone or in conjunction with other viral proteins) in this phenomenon, pUL69 favors sustained proliferation of CTH cells in parallel with low sustained viral growth in culture which have been reported as key elements for the transforming capabilities of the two oncogenic herpesviruses EBV and KSHV (25).

In addition to the role of pUL69 in low level viral replication detected in CTH cell cultures, it might also be directly involved in the oncogenic process fueled by HCMV. Notably, the functions of several cellular proteins involved in anti-viral responses and oncogenesis are under the control of certain modifications caused by the small ubiquitin-like modifiers (SUMOs), referred to as SUMOylation. These modifications can change the stability or localization of a specific protein and are capable of enhancing protein-protein interactions through the binding process of SUMOs to the SUMO-interacting sequences (SIMs) (39, 40). SUMOylation acts as a fundamental controller of cell cycle progression, genome stability, senescence, gene expression, stress, and innate immune responses (39, 41, 42). SUMO signal transduction has been identified as a key factor in the development of various cancer types, and SUMOylation was shown to be highly upregulated in several malignancies including breast cancer (39, 43–45). A recent report indicates that pUL69 has a SUMO E3 ligase activity and it can potentially bind to SUMO and Ubc9 (46). Besides, pUL69 takes over the induction of p53 SUMOylation when in complex with Ubc9 and SAE (46). Moreover, in Kaposi’s sarcoma-associated herpesvirus (KSHV), K-bZIP represents a SUMO2/3-specific E3 ligase, leading to its own SUMOylation in addition to that of p53 and Rb (47). Since pUL69 protein present in CTH cells possesses an E3 ligase activity, it might induce the inactivation of p53 through SUMOylation, thereby potentially leading to the development of cancer. In addition, a virally-encoded deSUMOylase activity is required for HCMV reactivation from latency (48). In line with the fact that SUMOylation is involved in HCMV latency, it is often considered as a prerequisite for cellular transformation by herpes oncoviruses (7, 25). It should be pointed out that the binding of pUL69 to PRMT6 could be another mechanism elucidating its role in cancer development. We previously noted the upregulation of PRMT6 gene expression in HCMV-infected HMECs (5). The binding of pUL69 to PRMT6 could favor oncogenesis as already reported with the upregulated expression of PRMT6 in prostate cancer (17, 49). Therefore, the multifunctional pUL69 protein might play a complex role in controlling CTH cell transformation. Future studies adopting *UL69* deletion and/or point mutation constructs and *UL69*-defective HCMV might further assess its direct (or indirect) role in oncogenesis.

**TABLE 3 |** Correlation between *UL69* Ct value and tumor grade (Elston-Ellis), tubule formation, nuclear pleomorphism and mitotic count in breast cancer biopsies.

	Correlation between <i>UL69</i> Ct value and			
	Tumor grade	Tubule formation	Nuclear pleomorphism	Mitotic count
<b>All Tumor Biopsies</b>	0.22 (p>0.05)	0.53 (p=0.038)	<i>Rho</i> 0.12 (p>0.05)	-0.12 (p>0.05)
<b>Luminal Biopsies</b>	0.109 (p>0.05)	0.62 (p=0.05)	0.50 (p>0.05)	-0.29 (p>0.05)
<b>Basal Biopsies*</b>	NA	NA	-0.89 (p=0.05)	NA

\*Since the values for Tumor grade, Tubule formation and Mitotic count in Basal biopsies are constant, the covariance of both variables is zero. Since a non-null covariance is required for correlation tests, the correlation cannot be applied to these constant values, making the correlation coefficient undefined.

It is worth noting that in macrophages, interferon (IFN) production is inhibited through ICP27-mediated interaction with the active stimulator of interferon genes (STING) signalosome. Knowing that UL69 protein represents the HCMV homolog of ICP27, it compromises the STING signaling pathway and type I IFN production, which might favor viral immune evasion and further cancer cell proliferation and migration (50, 51). Furthermore, a previous study indicated a potential role of the viral immunomodulator cytokine IL-10 during HCMV infection in enhancing breast tumor development and metastasis (52). Likewise, HCMV IL-10 exposed MCF-7 human breast cancer cells showed a significant up-regulation of matrix metalloproteinase-10 (MMP-10) gene expression, thus promoting excessive proliferation and tissue invasion (53).

Although *lncRNA4.9* has been shown to physically interact with the HCMV latent viral chromosome (54), we previously reported the presence of HCMV *lncRNA4.9* gene in breast cancer biopsies (6). In the present study, we detected the presence of the nearby *UL69* gene in breast cancer biopsies. A lower detection of the *UL69* gene (as measured by the percentage of *UL69* positive samples) was observed in breast tumor tissue compared to paired healthy breast tissue, in agreement with the previously reported block of HCMV replication in tumor tissue (55, 56). Since HCMV is detected in both tumor tissue and healthy tissue present in the vicinity of the breast tumor, the presence of HCMV in epithelial cells, tissue macrophages, or endothelial cells in normal breast tissue could fuel cellular transformation leading to breast cancer in some patients.

In conclusion, our findings highlight the potential of a clinical HCMV strain, namely the HCMV-DB isolate, to fulfill all the requirements contributing to the transformation of HMECs *in vitro*, causing the genesis of CTH cells. HCMV could possibly induce transformation through viral gene expression, including the *UL69* gene, which has been hijacked by latent and/or lytic viral cycle toward cellular transformation. The presence of *UL69* DNA in the majority of biopsies isolated from women with breast cancer indicates a potential relevance of *UL69* gene in breast cancer pathophysiology. The study of the *UL69* gene in CTH cells could be relevant to understand the molecular mechanisms involved in the development of breast cancer.

## DATA AVAILABILITY STATEMENT

The datasets presented in this study can be found in online repositories. The names of the repository/repositories and accession number(s) can be found in the article/Supplementary Material.

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by the study was approved by the local ethics committees of Besançon University Hospital (Besançon, France) and the French Research Ministry (AC-2015-2496, CNIL n°1173545, NF-S-96900 n°F2015). Genomic DNA isolated from biopsies of breast cancer patients (n=30) was provided by the regional tumor bank (BB-0033-00024 Tumorothèque Régionale de Franche-Comté). The patients/participants provided their written informed consent to participate in this study.

## AUTHOR CONTRIBUTIONS

SH, FAM, RB, ZN, SP, AK, FM and CM performed experiments. SP, GH, RK, M-PA, MD and TS participated to the data analysis. GH conceived and designed the project. SH, RB, SP and GH wrote the manuscript. All authors contributed to the article and approved the submitted version.

## FUNDING

This work was supported by grants from the University of Franche-Comté (CR3300), and the Région Franche-Comté (2020-11890). The funders had no role in the data collection, analysis, patient recruitment, or decision to publish.

## SUPPLEMENTARY MATERIAL

The Supplementary Material for this article can be found online at: <https://www.frontiersin.org/articles/10.3389/fonc.2021.627866/full#supplementary-material>

**Supplementary Figure 1** | Blast analysis of *UL69* nucleotide sequence. Comparison of *UL69* gene sequence present in CTH cells (Query) to the wild type HCMV-DB (Subject).

**Supplementary Figure 2** | Assessment of pUL69 protein expression and HCMV growth in MRC5 cells treated with UL69 siRNA and siRNA scramble. (A) pUL69 expression and (B) HCMV growth were monitored 24 hours post transfection with siRNA in HCMV-DB infected MRC5 cells by western blot and detection of IE1 in culture supernatants by qPCR assay, respectively. Results are representative of two independent experiments.

Human cytomegalovirus (HCMV) is a highly prevalent herpesvirus that persistently infects a significant portion of the global population. Despite robust host immune responses, HCMV has evolved multiple immune-modulatory strategies to replicate, evade host defenses, and establish lifelong latency. It achieves this by impairing the expression of HLA Class I and II molecules, evading natural killer cell-mediated cytotoxicity, interfering with cellular signaling, inhibiting apoptosis, escaping complement attack, and inducing immunosuppressive cytokines. HCMV also expresses various gene products that modulate the host immune response and affect non-coding RNA and regulatory proteins. These immune evasion strategies are associated with complications such as immunosenescence and malignant phenotypes, resulting in an immunosuppressive tumor microenvironment and oncomodulation. Consequently, HCMV's role in promoting tumor survival involves influencing cellular proliferation, survival, invasion, immune evasion, immunosuppression, and the production of angiogenic factors. Understanding HCMV's immune evasion mechanisms is crucial for developing adapted therapeutic approaches, particularly in the era of immunotherapy, which has transformed cancer treatment. By employing multimodal strategies that induce immunogenic tumor apoptosis and counteract the immune-suppressive microenvironment, it may be possible to enhance anti-tumor immunity.

Human Cytomegalovirus (HCMV) is an immensely pervasive herpesvirus, persistently infecting high percentages of the world population. Despite the apparent robust host immune responses, HCMV is capable of replicating, evading host defenses, and establishing latency throughout life by developing multiple immune-modulatory strategies. HCMV has coexisted with humans mounting various mechanisms to evade immune cells and effectively win the HCMV-immune system battle mainly through maintaining its viral genome, impairing HLA Class I and II molecule expression, evading from natural killer (NK) cell-mediated cytotoxicity, interfering with cellular signaling, inhibiting apoptosis, escaping complement attack, and stimulating immunosuppressive cytokines (immune tolerance). HCMV expresses several gene products that modulate the host immune response and promote modifications in non-coding RNA and regulatory proteins. These changes are linked to several complications, such as immunosenescence and malignant phenotypes leading to immunosuppressive tumor microenvironment (TME) and oncomodulation. Hence, tumor survival is promoted by affecting cellular proliferation and survival, invasion, immune evasion, immunosuppression, and giving rise to angiogenic factors. Viewing HCMV-induced evasion mechanisms will play a principal role in developing novel adapted therapeutic approaches against HCMV, especially since immunotherapy has revolutionized cancer therapeutic strategies. Since tumors acquire immune evasion strategies, anti-tumor immunity could be prominently triggered by multimodal strategies to induce, on one side, immunogenic tumor apoptosis and to actively oppose the immune suppressive microenvironment, on the other side.

**Keywords:** HCMV, immunosuppression, immune evasion, immunosenescence, TME, oncomodulation, therapeutic approaches

## BACKGROUND

HCMV or human herpesvirus 5 (HHV-5) has co-evolved with mammalian hosts over millennia infecting almost 83% of the world's population, impending 100% in developing countries (1). After initial infection, HCMV can establish lifelong persistence within its corresponding host as well as possessing the reactivation potential; viral persistence depends on composite interactions among various

viral and host determinants. Such interactions mostly generate an equilibrium between the immunocompetent host and the virus itself. In the host, HCMV infrequently causes symptoms unless this balance is demolished by the minimized host immune proficiency (atypical settings) leading to substantial pathology (1, 2). Upon viewing several forms of viral-host interaction, the explicit HCMV reactivation in immunosuppressed patients (organ transplant recipients) and immunocompromised patients (septic patients, elderly, HIV-infected patients, etc.) is considered a well identifiable disease state (3, 4). Hence, in immunocompetent patients, HCMV is considered a multifaceted beta herpesvirus that is viewed as an asymptomatic and mildly pathogenic virus, but may nevertheless cause chronic infections along with acute and serious complications in immunocompromised individuals (5). HCMV persistence can also have a key influence on the host, even in healthy carriers, through the attenuation of innate and adaptive immune responses since HCMV starts to counteract several host immune response mechanisms required to control the infection (1, 2). HCMV potentially triggers the host immune responses starting by the mechanisms of innate immunity, including inflammatory cytokines resulting from virus/cell binding and NK cell induction which consequently drives adaptive immune responses, involving production of antibodies and the initiation of CD4<sup>+</sup> and CD8<sup>+</sup> T-cell responses. However, HCMV encodes various immune evasion mechanisms; hence, expressing several genes that influence both innate and adaptive immunity (5, 6).

HCMV, a leading viral cause of birth defects, has been linked to several mortality and morbidity conditions (7). The stage of HCMV acquisition may affect the range of associated clinical manifestations and the effectiveness of the immune responses exerted against HCMV (7, 8). Regarding congenital CMV infection, neurological defects might be experienced as mental retardation, cerebral palsy, and hearing impairment; newborns may experience either symptomatic or asymptomatic infections (7, 9, 10). Symptomatic infections might cause petechiae, low birth weight, jaundice, hepatosplenomegaly, seizures, and microcephaly; they appear to be more common in newborns infected during the first trimester of pregnancy (7). In case of premature birth, sepsis and respiratory distress can develop (11). Compared to adults, these observations indicate that controlling CMV replication is restricted during early stages of life and is associated with delayed immune responses and increased risk of symptomatic infection (7). Years later, persistent HCMV infection might be considered a potential risk factor exacerbating age-associated diseases and immunosenescence which is defined as the age-associated deterioration in overall immune condition (12–14) although some studies have indicated that the link between HCMV and immune aging is obscure (3, 15). Further, various stimuli can induce HCMV reactivation; it might be triggered in SARS-CoV-2 infected patients (16, 17) thus exacerbating the risk of coronavirus disease 2019 (COVID-19) (18, 19). Even if this interaction is still elusive and additional large scale studies are recommended (16), CMV testing and treatment should be taken into consideration in such critical conditions (18). CMV status must be taken into account for several vaccine responses, especially cancer despite the use of

HCMV-based therapeutic cancer vaccines (20), since it has been suggested that with advanced age and due to CMV-associated altered immunity in both healthy and immunocompromised hosts, vaccine immunogenicity was modulated (21–23). Thus, recent studies are concerned about targeting HCMV to decrease the sensitivity to other infectious diseases and cancer, and to prevent poor responses to vaccination (21, 22).

The contribution of HCMV infection in late inflammatory complications highlights its potential association with chronic diseases, such as atherosclerosis, chronic rejection following solid-organ transplantation, and malignancies (24). Recent investigations have reported the prevalence of HCMV infection in tumoral tissues of malignancies such as malignant glioma, breast and colon cancer, negative Hodgkin's disease, Epstein-Barr virus (EBV), liver cancer, cervical cancer, and prostatic carcinoma (1, 25, 26). Despite the fact that HCMV is not yet included in the oncogenic viruses list, its possible contribution in carcinogenesis as initiator or promoter is significantly reported suggesting that HCMV and tumors express a symbiotic relationship (26–29). HCMV aids the tumor to escape immune surveillance by encoding viral proteins and inducing various cellular factors, in addition to the HCMV-induced immune tolerance which favors tumor growth. In return, HCMV harbors in the immunologically weak environment of the cancerous cells (6). This review accentuates the considerable influence of HCMV on the immune landscape and its oncomodulatory signals that might contribute to oncogenesis.

## HOST IMMUNE RESPONSES AGAINST HCMV INFECTION

HCMV, a double-stranded DNA (dsDNA) genome beta-herpesvirus is considered the largest virus among the human herpesviruses (30). Upon HCMV infection and despite the counteracting host response, this virus powerfully adapts to the human immune system. HCMV is certainly not eradicated from the HCMV-positive immunocompetent patient, in whom the virus establishes latency (31). Thus, the human immune system is incompetent to clear the latent HCMV, however it mounts an immune defense targeting multiple viral proteins (8). Due to the existing coevolution between HCMV and the host immune system for millions of years, it's informative to study the immune defense strategies and pathogen counterstrategies (12). Innate immunity, in addition to adaptive humoral and cell-mediated immune responses, are induced by HCMV infection; such responses lead to the resolution of acute primary infection (5). Such immune responses differ during distinct life stages; throughout pregnancy, maternal anti-HCMV antibodies participate in preventing congenital fetal CMV infection (32). In addition, studies have shown that despite the detection of primary humoral and cellular immune responses in neonates, cell-mediated immune responses are delayed compared to adults which justifies the reason behind uncontrolled viremia and serious clinical harm in early life CMV infections (8, 32, 33). CMV-specific CD8<sup>+</sup> T-cell responses in congenitally infected newborns were characterized by lower IFN- $\gamma$  levels and elevated

levels of IL-8 compared to adults (33). Finally, elderly people have increased sensitivity and susceptibility to serious infections and diseases most likely due to immunosenescence (14).

### HCMV Entry

HCMV exhibits a wide host cell range, possessing the ability to infect several cell types for instance endothelial cells, epithelial cells, fibroblasts, smooth muscle cells, leukocytes, and dendritic cells (DCs) (8, 34). In healthy persons, HCMV initiates its replication in the mucosal epithelium; thereafter, it disperses to monocytes and CD34+ cells, where it institutes a latent infection. Upon differentiation of HCMV-infected monocytes into macrophages, a viral infection could be initiated (35). Infection of both hematopoietic and endothelial cells systemically eases the viral spread within the host (36), unlike prevalent cell types infection including smooth muscle cells and fibroblasts which enhances efficient proliferation of the virus (35).

### Innate Immunity

As HCMV enters the cells, virions are firstly recognized by the host thus activating multiple pathways and strategies of innate immunity which is known as the primary host defense against HCMV infection (8). These involve inflammatory cytokines, type I interferon (IFN), and upregulation of CD80 and CD86 (37) that are essential for limiting pathogen's spread and thereafter priming the adaptive immune response (5, 8). The stimulation of the NF- $\kappa$ B pathway and predominant inflammatory cytokines production for example interleukin-6 (IL-6) and tumor necrosis factor-alpha (TNF- $\alpha$ ) (38) result from the interaction of viral envelope glycoproteins B (gB) and glycoprotein H (gH) with the immune-sensor molecules namely, toll-like receptors 2 (TLR2) (5, 12, 39, 40). Such inflammatory cytokines are capable of inducing and triggering phagocytic cells, such as dendritic cells, which have the ability to clear HCMV-infected cells (5, 8, 38). In the initial infection sites, NK cells are activated to eradicate HCMV-infected cells by the liberation of cytotoxic proteins (38). Furthermore, studies have shown NK cells' role in inhibiting HCMV transmission in fibroblasts, epithelial, and endothelial cells and this through inducing IFN- $\beta$  in target infected cells (41) and secretion of IFN- $\gamma$  (42). NK cells, crucial guards of the immune system, produce a cytokine environment that triggers the consequential maturation of adaptive immune responses particularly T-cells (5, 8, 43).

### Adaptive Immunity

The adaptive immunity which contributes to the control of HCMV infection is among the strongest responses in which it fully engages humoral and cellular immune responses. Adaptive immunity is necessary to fundamentally manage HCMV primary infection, afterwards HCMV will enter into a latent state (44). The development of a sustained adaptive immune response is essential to preserve HCMV latency, avert acute viremia, and avert lytic infection which, in contrast, is frequent in patients on immunosuppressive therapies and immunocompromised individuals often leading to unrestricted replication and clinically severe HCMV morbidity and mortality (45).

### Humoral Responses

Following a primary HCMV infection, the initiation of a robust immune response to control HCMV is essentially required. Many evidences supported the role of humoral immunity in limiting viral propagation and HCMV severity through antibody production targeting multiple CMV proteins, envelope glycoproteins, and genes (8, 32). The key target for antibody neutralization against HCMV is gB since it is related to cellular adhesion and invasion; besides, gH is considered the secondary target as it is involved in the fusion of the host cell membrane with the viral envelope (37). Other targets include the structural tegument proteins (pp65 and pp150) and non-structural proteins (IE1) (8, 32). A study shows that pregnant women, primarily infected with HCMV, having HCMV specific IgM antibodies and missing neutralizing IgG antibodies are at greater risk of transmitting HCMV to their fetus in contrast to seropositive mothers experiencing a recurrent infection (45). Thus, underlying the critical role of humoral immunity, especially HCMV IgG, in controlling HCMV infection and spread.

### T-Cell Mediated Immune Responses

Due to the fact that the immune response stimulated by primary infection does not eliminate HCMV, HCMV-specific CD4<sup>+</sup> T-cells, CD8<sup>+</sup> T-cells, and gamma delta ( $\gamma\delta$ ) T-cells have been considered as critical players in restricting viral replication in hosts acquiring persistent infections (38, 46, 47). With regard to CD8<sup>+</sup> T-cells, the CD8<sup>+</sup> HCMV-specific T-cell response is targeted toward HCMV proteins which are being expressed at different stages of viral replication (IE, early, early-late, and late) in addition to other proteins possessing various functions (capsid, tegument, glycoprotein, DNA-regulatory, and immune escape) (37). It is worth noting that the most immunodominant antigens to which HCMV-specific CD8<sup>+</sup> T-cells react are addressed toward IE1 (UL123), IE2 (UL122), and pp65 (UL83) (37, 48). Even though the major histocompatibility complex (MHC) class I-restricted CD8<sup>+</sup> T-cell immune response role in targeting HCMV is evidently marked, there exists a significant indication that CD4<sup>+</sup> T-cells are as well fundamental in controlling HCMV infections (37). Further studies reveal the attainment of a cytolytic potential by pp65-specific CD4<sup>+</sup> T-cells and gB-specific CD4<sup>+</sup> CTL *in vivo* where CD4<sup>+</sup> T-cells released granzyme B in reaction to glia presenting endogenous gB (49). The recruitment of HCMV-specific T-cells into the memory compartment is stimulated by the relatively prolonged viral replication of HCMV since T-cells are mandatory to limit HCMV viral replication and impede certain diseases (50). HCMV-specific T-cell responses inflate throughout life leading to a significant fraction of memory T-cells in healthy seropositive individuals (50–52). Hence, HCMV-seropositive immunocompetent people maintain lifetime protection despite the insufficient or minimal HCMV-specific T-cell responses. Cellular responses from CD4<sup>+</sup> and CD8<sup>+</sup> T-cells vary among individuals (50). HCMV-positive serostatus has been associated with CD8<sup>+</sup> T-cell compartment expansion, reduced CD4:CD8 T-cell ratio as well as alterations in the expression of CD8+ T-cell senescence related markers (53, 54). These senescent cells are characterized by a progressive loss of CD28 and CD27,

upregulation of CD57 expression which is known as the classical immune senescence marker, replicative senescence, and shortened telomeres resulting in a limited cell proliferation capacity and finally the inability to eliminate the HCMV infection (14, 55). Other cellular responses include  $\gamma\delta$  T-cells and NK cells. Although the previously mentioned cells are not targeted specifically against HCMV, they can still successfully lyse HCMV-infected endothelial cells and fibroblasts in consequence of a cellular stress response that upregulates the endothelial protein C receptor (EPCR) in addition to CD54 (Intercellular adhesion molecule-1, *ICAM-1*) (56).  $\gamma\delta$  T-cells contribute to dual immune response, anti-infectious and antitumor. Activated  $\gamma\delta$  T-cells are essential immune effectors against HCMV in which they stimulate IFN- $\gamma$  and TNF- $\alpha$  production that may synergize to inhibit HCMV replication (38).

### HCMV PERSISTENCE DESPITE ANTIVIRAL IMMUNITY

In healthy individuals, the operative homeostatic equilibrium established between HCMV and the host prevents serious HCMV complications. Conversely, in an immunocompromised host, fetus, and neonates, HCMV infection can cause multiple forms of clinical harm (8). Disequilibrium in immunocompromised patients can result in unhindered viral replication followed by the reactivation of the latent virus, with subsequent morbidity and mortality (5). Despite a powerful immunity involving both arms of the immune system, HCMV establishes latency. In that context, HCMV-encoded determinants of tropism for endothelial cells, an imperative objective of the infection, were considered. It was stated that in endothelial cells the UL133-UL138 locus, encoded in the ULb' region of the HCMV genome, is essential for the viral late-stage response (57). In infected cells, this locus was mandatory for preserving membrane organization and is required for the progeny viruses' maturation. However, it's not necessary for early/late gene expression or viral genome synthesis. Viruses missing the *UL133-UL138* region, produce progeny viruses that are deprived of tegument and envelopes, leading to deficient viral yields. *UL135* and *UL136* genes, encoded in the UL133-UL138 region, promote viral maturation. Additional recent data propose that this locus involves the main molecular switch among latency and reactivation, including the opposing roles of *UL135* and *UL138*. Moreover, a study reported that the outcome of antiviral immunity might be influenced by numerous viral determinants, including HCMV strain, virulence, MHC I downregulation, and other escape strategies elicited by HCMV during the early virus-host interaction (3).

### HCMV ESCAPE MACHINERIES AND IMMUNOSUPPRESSION

HCMV has evolved manifold immune evasion strategies that modulate the host immune system and promotes more efficient infection and dissemination within the host. A chief evasion strategy depends on hindering the MHC class I-restricted

antigen presentation (58). Throughout the immediate early HCMV infection phase, a cytotoxic T-lymphocyte (CTL) response counteract antigenic peptides resulting from the IE1 transcription factor (59, 60). The matrix protein, pp65, possessing a kinase activity, phosphorylates the IE1 protein and specifically inhibit the presentation of IE-derived antigenic peptides to escape immune recognition of the early produced viral proteins (59). Knowing that pp65 is delivered directly into the cells during the viral fusion phase, HCMV will instantly escape from immunological surveillance, till further immune evasion related proteins are secreted (61). HCMV-specific viral proteins and genes that are associated with the host interferon responses (pp65), inhibit NK cell detection or activation (37, 62), and inhibit the recognition of CD4<sup>+</sup> and CD8<sup>+</sup> T-cell by preventing MHC Class I and II antigen processing and appearance (1, 37, 61). HCMV infected cells produce viral IL-10 homolog which further suppresses CD4<sup>+</sup> and CD8<sup>+</sup> T-cell responses (1, 61). The previously mentioned evasion mechanisms are summarized in **Figure 1**.

In the absence of MHC class expression, HCMV must be susceptible to NK cell-mediated lysis; however, HCMV donates a large proportion of its genome to down-regulate the NK cell activity (63). Consequently, the surface expression of HLA-E and HLA-G is stimulated by gpUL40 and CMV-IL10 respectively (64–66). In addition, the expression of UL16 supports HCMV to block natural killer group 2D (NKG2D)-mediated NK-cell activation and this is by adopting a blocking strategy that hinders the binding of NKG2D to UL16 binding proteins (ULBPs) namely, ULBP1 and ULBP2, and to the MHC class I chain-related gene B (*MICB* gene) (37, 61). HCMV US18 and US20 proteins stimulate the deterioration of a major stress protein namely, MHC class I polypeptide-related sequence A (*MICA*); hence, preventing the NK cell from recognizing infected cells' stress signals (67). Other machineries considered by HCMV to escape NK cell lysis involve the inhibition of NK cell-activating receptor (NKP30) by pp65 (37), UL122-encoded microRNA that represses *MICB* gene expression (68), and blocking of the expression of CD155 by HCMV-UL141 (37).

To counteract apoptosis and further evade the immune system, HCMV overexpresses anti-apoptotic proteins and inhibits pro-apoptotic molecules and death receptors. The former is achieved by upregulating B-cell lymphoma 2 (*Bcl-2*) in HCMV-infected cells (69) and expressing Fas-associated death-domain-like IL-1 $\beta$ -converting enzyme-inhibitory proteins (FLIP) by IE2 (70). On the other hand, pUL36 inhibits the induction of procaspase 8 to the death-inducing signaling complex (DISC) and pUL37 inhibits pro-apoptotic Bcl-2 members namely Bcl-2-associated X Protein (*Bax*) and Bcl-2 homologues antagonist/killer (*Bak*); thus, HCMV is hindering apoptosis through two distinct mechanisms (6, 61). Furthermore, HCMV has developed UL36 and UL37 proteins, which enhance the survival of infected cells; thus, stimulating viral dissemination within the host (37, 71). HCMV escapes complement attack by upregulating the host-encoded complement regulatory proteins (CRPs) (72) and by the ability of HCMV to integrate host cell-derived CRPs, CD55 and CD59 in its virions (6).

Lastly, HCMV produces the G-Protein-coupled receptors (GCRs) homologs US27, US28, UL33, and UL78 that might act as eliminators of chemotactic factors, thus hindering the inflammatory cells' accumulation at the viral infection site (61, 73). These viral approaches secure novel viral progeny production and facilitate the spread to other hosts (61). US28 is usually expressed in the early infection phase; it shows the highest homogeneity to the CC chemokine receptor CCR1. It also binds the CC chemokines RANTES, monocyte chemoattractant protein-1 (MCP-1), monocyte chemoattractant protein-3 (MCP3), macrophage inflammatory protein-1 alpha (MIP-1 $\alpha$ ), and macrophage inflammatory protein-1 beta (MIP-1 $\beta$ ), in addition to the membrane-associated CX3C chemokine, fractalkine (37, 61, 74). US28 expression results in the stimulation of phospholipase C and NF- $\kappa$ B signaling. The US28-fractalkine interaction has been involved in cell targeting and viral dissemination (61). The transcription of *US28* takes place during productive and latent HCMV infection, which might justify the dissemination of latent HCMV (75, 76). Moreover, HCMV encodes a homolog of the immunosuppressive cytokine IL-10 (UL111a) (62, 71); it likewise possesses potent immunosuppressive traits, including the inhibition of mitogen-stimulated peripheral blood mononuclear cells (PBMCs) proliferation in addition to the blockade of pro-inflammatory cytokine synthesis in PBMCs and monocyte (37,

61). CMV IL-10 binds to the cellular human receptor of IL-10 despite its minimal homology to the endogenous cellular IL-10 (61). In addition, HCMV establishes immune tolerance by inducing the transcription and release of TGF- $\beta$  which inhibits anti-viral IFN- $\gamma$  and TNF- $\alpha$  cytokine production and cytotoxic effector activities of HCMV specific Th1 cells (77). Further homologs encoded by HCMV are UL144 which is a viral TNF receptor and an effective IL-8-like chemokine (viral CXC-1) prompting the chemotaxis of peripheral blood neutrophils (UL146) (37). Lastly, HCMV strategies that modify the cellular infected environment to restrict immune identification are known to be widely expressed during lytic infection; however, recent evidence shows that viral genes' activity in preventing immune recognition is being remarkable even during latency phases (75). Recent data shows that the majority of the HCMV-encoded proteins and microRNAs (miRNAs) are expressed also during latent stages (75, 76) (Table 1 and Figure 1).

### HCMV COMPLICATIONS UNDER IMMUNOSUPPRESSION

The suppressive effects exerted by HCMV on the host immune system, HCMV persistence, dissemination, and reactivation result

in dire consequences. The severe and mortal complications resulting from HCMV reactivation mainly occur in immunosuppressed and seriously ill immunocompetent individuals in whom the HCMV infection is accompanied by prolonged hospitalization and/or mortality. Furthermore, the manipulation of the host immunity can result in superinfections with other herpesviruses or bacteria, and exacerbate SARS-CoV-2 infections that are benefiting from the weakened immune system (18, 19, 103, 104). Since HCMV infection is known as a prevalent congenital viral infection, it might generate viral hepatitis with jaundice in addition to long-lasting disabilities, including hearing and visual damage, neurological impairments, and mental retardation (103). Additionally, studies show that HCMV has been detected in tissue specimens from immunocompetent individuals with inflammatory diseases, including atherosclerosis, psoriasis (6, 105), rheumatoid arthritis (24), inflammatory bowel disease (IBD) (105), and systemic lupus erythematosus (SLE); it has been concerned in the development of these diseases (103). HCMV leads to the development of restenosis after coronary angioplasty, chronic rejection of organ transplantation, chronic graft-versus-host disease in recipients of bone marrow transplants (24). Such observations infer the presence of an association between HCMV and autoimmune diseases. Knowing that the HCMV chemokine receptor homolog, US28, is considered a major co-receptor for several HIV strains, it provokes cell fusion with several forms of viral envelope proteins in addition to stimulating HIV-1 entry into HCMV-infected cells (106). Several epidemiologic studies suggested that HCMV infection has been linked to an elevated risk of cardiovascular death, one of which revealed that CMV seropositivity has been significantly associated with cardiovascular mortality ( $P$ -value=0.007) (107). This association was confirmed by another study showing an “increased six-year cardiovascular mortality” ( $P$ -value=0.021) (108). Further findings showed that CMV seropositive elderly presented elevated cardiovascular mortality compared to CMV-negative ones; the subhazard ratio for cardiovascular mortality was 1.95 (95% CI: 1.29–2.96,  $P$ -value=0.002) (109). The association between HCMV and vascular diseases is verified by the transient presence of US28 in smooth muscle cells which induces chemokinesis and chemotaxis (61). Moreover, since HCMV infection has been involved in producing modifications among the total T-cell population and adversely affecting to the immune well-being of elderly, it stimulates the occurrence of numerous age-related syndromes, and decreases efficacy of vaccines (3, 12, 110). Additionally, in elderly, HCMV could contribute to inflammation-mediated vascular pathology which is evaluated by determining systemic inflammation markers (C-reactive protein, IL-6, and TNF) and it might also cause direct vascular damage (2).

### HCMV ONCOMODULATION AND ITS SIGNIFICANCE IN TUMOR MICROENVIRONMENT

Alterations resulting from cancerous genetic and epigenetic instability provide recognizable antigens that are distinguished

by the host immune system (111, 112). As cancer evolves, it can resist immune clearance by prompting tolerance in the presence of tumor-associated inflammatory cells (113). Consequently, a tumor microenvironment is generated and controlled by tumor-induced molecular and cellular interactions (114) in which immune cells not only fail to exert anti-tumor effector functions, but also promote tumor development (113). Since CMV possesses different cellular signaling pathways, encodes many genes that exhibit immunosuppressive effects, and may empower cancer hallmarks, it thus plays an essential role in generating cancerous cells and has a fundamental impact on the tumor microenvironment (1, 29, 115).

Some studies put extra emphasis on the indirect role of CMV in cancer (115, 116). For instance, Dey et al. suggested that the association between glioma and CMV is an “observational association” (117). However, the prevalence of HCMV is remarkably high in several cancer forms (26, 118). Several research groups showed that over 90% of breast, colon, and prostate cancer, rhabdomyosarcoma, hepatocellular cancer, salivary gland tumors, neuroblastoma and brain tumors were positive for HCMV nucleic acids and/or proteins (26). HCMV DNA was confirmed in 100% of breast cancer and 91% of sentinel lymph nodes samples from the metastatic group (119). Moreover, a study conducted by Taher et al., showed HCMV detection in 98% of breast cancer derived metastatic brain tumors, suggesting a potential link between HCMV and metastatic cancer (120). HCMV was considered as a potential therapeutic target in metastatic cancer due to the expression of HCMV-IE protein in 53% of breast cancer samples which therefore resulted in shorter overall survival, and the detection of HCMV DNA and transcripts in 92% and 80% of the used specimens respectively (120). Another study showed the inversely proportional relation between HCMV-IE1 presence and hormone receptor expression suggesting HCMV role in hormone receptor-negative breast cancer tumors (121). HCMV IE1 and pp65 were present in 82% and 78% of colorectal cancer samples, and in 80% and 92% of adenocarcinomas, respectively. In colon cancer cells, these HCMV-specific proteins contribute to the induction of Bcl-2 and COX-2 proteins thus promoting colon cancer progression (122). Cobbs et al. showed that HCMV-IE1 was expressed in all studied glioma biopsy specimens, in all grades (II-IV) (123). Over again, HCMV-IE and late proteins were expressed in 100% and 92% of primary neuroblastoma samples respectively; notably, HCMV proteins were detected in CD133 and CD44-positive neuroblastoma cells (118). HCMV DNA was detected in the peripheral blood of GBM patients (80%), suggesting either HCMV reactivation or viral DNA shedding from HCMV-tumor cells (124). In addition, HCMV was detected in all evaluated preneoplastic and neoplastic prostate lesions (125). In Hodgkin’s disease cases, the HCMV infection frequency was 28.6% (126). Further, expression of HCMV was marked in the neoplastic epithelium of 97% of the carcinoma patients (127). 92% of the primary medulloblastoma cases expressed HCMV-IE protein while 73% expressed late viral proteins (128). Evident elevated survival rates were observed among HCMV positive glioblastoma patients who

were on anti-viral therapy (valganciclovir) (120, 129). A 70% and 90% survival rate was proved with 6-month and continuous valganciclovir treatment, respectively (120). Despite the existing studies which describe the possible involvement of CMV in cancer, further large scale investigations are needed in addition to the necessity of novel epidemiologic studies knowing that the latter might be challenging to conduct especially among CMV-positive cancer patients.

HCMV infects multiple cell types including stem cells; referring to the fact that Thy-1 and platelet-derived growth factor receptor alpha (PDGFR $\alpha$ ) stem cell markers enhance HCMV infection, stem cells are susceptible to HCMV infection

(130, 131). Thus, stem cells serve as reservoirs for HCMV persistence and reactivation. The major stem cell regulator namely, Wnt tends to trigger HCMV transcriptional activation; hence, once HCMV disseminates to various body organs, viral expression occurs during patients' lifetime in stem cells (132). It is worth noting that the latter increases the chance of accumulation of genetic mutations; thus, stem cells lose control over their self-growth and renewal, act as a cancer source, and become susceptible to oncogenesis in the presence of inflammation and altered DNA repair pathways (133). In return, HCMV can support stem cells survival which would potentially elevate oncogenesis. Studies reveal the effect of

HCMV-IE1 protein in promoting the preservation of glioblastoma cancer stem cells through its induction of SRY-Box Transcription Factor 2 (SOX2), Nanog, Nestin, and octamer-binding transcription factor 4 (OCT3/4) where it's considered as a key regulator of glioblastoma stem-like phenotype (134). In GBM cells, the induction of transcription factors that are crucial for cancer stem cell persistence, cancer growth, and signaling pathways associated with the epithelial to mesenchymal (EMT) phenotype are stimulated by HCMV IE1 expression (134, 135). Many studies proved that cancer stem cells infected with HCMV possess a progression potential in contrast to HCMV-negative cancer stem cells. Some HCMV strains, for instance HCMV-DB and HCMV-BL, are capable of transforming human mammary epithelial cells and producing a "transcriptional profile" associated with DNA hypomethylation that resulted in enhanced proliferation, activation of cancer stem cell, and EMT process (136, 137). Likewise, HCMV was proven to induce an EMT phenotype in colorectal carcinoma cells accompanied with amplified tumor proliferation and cancer cell invasion (136). In addition, IE1 expression was detected in CMV transformed HMECs (CTH) cells which as well express embryonic stem cell markers (138). HCMV IE1 and IE2 gene expression in addition to UL76 genes prompt DNA mutagenesis, chromosome breakage, and genomic instability. Such expression of HCMV gene products could affect the pathways of p53 and Rb tumor suppressors, and other pathways that are responsible for DNA repair (27, 139, 140). Presuming the role of HCMV gene products in causing DNA damage directly and indirectly, and stimulating proliferation in stem cells, HCMV may have the potential to initiate and promote tumor formation. The oncomodulatory potential of HCMV catalyzes an oncogenic process by producing viral proteins, helping tumor cells to evade the immune system, and preventing and/or delaying cell death. The lack of HCMV specific cellular immune responses in these immune-privileged tumor sites would definitely enhance HCMV replication. On the other hand, cancer cells on their own can escape immune responses by diverse mechanisms. Thus, the combination of intrinsic cellular with viral immune escape machineries in cancer cells may offer an environment which enhances HCMV replication and boost cancer cells to evade from immune surveillance showing the bidirectional relationship between tumor cells and HCMV (25, 141). It's worth mentioning that HCMV can activate many of the tumor pathways' hallmarks including uncontrolled inflammation, myeloid cells' infiltration, immune modulation, angiogenesis, and metabolic reprogramming. Production of inflammatory cytokines including RANTES, MCP-1, MIP-1a, IFN- $\gamma$ , TNF- $\alpha$ , IL-4, IL-18, and IL-8F is induced by HCMV (142, 143). The HCMV-US28 chemokine receptor strongly promotes the expression of the NF- $\kappa$ B, COX-2, IL-6, and p-STAT-3 which could initiate oncogenic pathways (144, 145). Upon HCMV infection of human cancer stem cells and in the presence of cmvIL-10, cancer stem cells can induce macrophage reprogramming "M2 phenotype" in the tumor microenvironment hence favoring the appearance of tumor-associated macrophages (TAMs) and enhancing other immunomodulatory, oncogenic, and

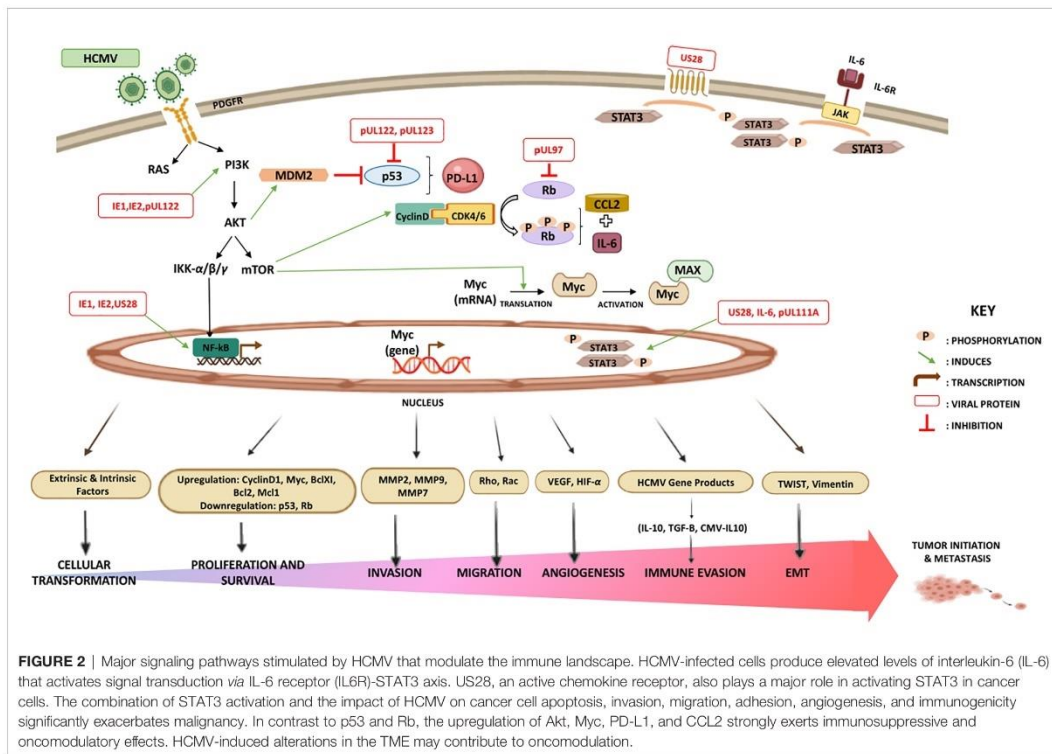

angiogenic cytokines' expression such as STAT3 and vascular endothelial growth factor (VEGF) (146–148). Similar to US28, the cmvIL-10 chemokine which is known to be expressed in latency phase and tumor cells can enhance cancer cell invasion (149). In addition, HCMV can guarantee neutrophils and mononuclear cells survival, which can support a quick oncogenesis *via* the activation of an angiogenic switch (150, 151). Further, long non-coding RNAs (lncRNAs) were described as efficient players not only in facilitating signal transductions in tumor signaling pathways but also in promoting tumor evasion from immunosurveillance. It has been also shown that immune cells for instance, T-cells, B-cells, dendritic cells, macrophages, and myeloid cells control tumor immune responses *via* lncRNAs linked pathways (152, 153). In CTH cells, HCMV lncRNA4.9 was formerly detected in tumors isolated from xenograft NSG mice injected with CTH cells, as well as in human breast cancer biopsies (137). Moreover, several studies specified that modifications in gut permeability and intestinal microbiota translocation can stimulate chronic inflammation as well as causing auto-immune and neoplastic diseases (154, 155). Knowing that CMV presence was associated with upregulation of various cytokines, elevated epithelial gut damage, microbial translocation, and systemic inflammation (156, 157), it might play a part in eliciting carcinogenesis. All in all, these studies indicate that HCMV can be actively involved in enabling cancer progression and this is through inducing certain pathways that give rise to epigenetic modifications, and promoting the activation of cancer stem cell, angiogenesis, invasion, and an EMT phenotype (136, 158, 159). Certainly, one of the limitations for assessing the effect of HCMV on immunity and cancer progression is that the majority of the investigations were done on the high risk CMV-positive subpopulation which might involve diverse immunomodulation sociodemographic and environmental co-factors other than HCMV status as well as divergent lifestyles and medical history. Therefore, prospective studies are highly required to rule out other immunomodulatory factors and precisely evaluate the impact of CMV on host immunity.

Nonetheless, it is noteworthy that the oncogenic potency of HCMV clinical strains varies between low and high-risk strains. HCMV-DB and HCMV-BL have been classified as high-risk strains in which they possessed their oncogenic potentials in acutely infected human mammary epithelial cells (HMEC) *in vitro* showing sustained transformation. These high-risk strains were characterized by elevated *Myc* expression, PI3K/Akt pathway activation, and *p53* and *Rb* gene repression (138). With regard to immune responses, *Myc* suppresses immune surveillance by modulating the expression of the innate immune regulator (CD47, also known as integrin-associated protein) and the adaptive immune checkpoint namely, programmed death ligand 1 (PD-L1, also known as CD274 and B7-H1) (160–164). Further, *Myc* regulates thrombospondin-1 (161) and Type 1 IFN (165, 166). Hence, *Myc* initiates and maintains tumorigenesis through the modulation of immune regulatory molecules. PI3K/Akt activation induced inflammation and immunosuppression through nitric oxide synthase (NOS) overexpression; thus,

resulting in tumor initiation *via* the activated Notch pathway leading to tumor progression (167). On the other hand, suppression or mutation of p53 has been shown to decrease MHC-I presentation, increase STAT3 phosphorylation, upregulate PD-L1 *via* microRNA (miR34), elevate pro-inflammatory chemokine and cytokine production, and indirectly upregulate the expression of chemokine receptors (CXCR4 and CXCR5) (160, 168, 169). Loss of Rb leads to the increase in CCL2 and IL6 secretion and this is because of the elevated fatty acid oxidation (FAO) activity and enhanced mitochondrial superoxide (MS) production (170). Indeed, those molecular alterations have been linked to immune suppression in the tumor microenvironment indicating that only high-risk HCMV strains possessing oncomodulatory properties are potentially involved in the oncogenesis process as described previously (84, 138) (Figure 2). In line with the previously presented epidemiological studies, and since HCMV was confined within tumors correlating positively to poor prognosis, as well as the potential of HCMV gene products in regulating tumorigenic pathways and processes linked to cancer hallmarks, and finally the HCMV broad tissue tropism, we infer that HCMV possesses distinctive mechanisms in cancer progression (26, 29, 171).

### THERAPEUTIC APPROACHES IN HIGH-RISK POPULATIONS

The fact that HCMV is highly prevalent in different cancer forms, opens up the possibility to manage such cancers with anti-HCMV medications. Currently, two major approaches are being chased; the first emphasizes on antiviral therapy while the other targets HCMV directed immunotherapy. The core approach to antiviral therapy involves the use of valganciclovir. The rationale behind using valganciclovir is suppressing HCMV replication in HCMV-positive glioblastoma (GBM) cells leading to the repression of virus-mediated tumor-promoting strategies. Despite its viral replication suppression, valganciclovir doesn't eradicate the virus. Thus, short-term valganciclovir treatment wouldn't be ideal for treating glioma patients, necessitating long-term treatment to maintain the tumor suppressive properties (116). Interestingly, valganciclovir treatment outcome was improved in combination with celecoxib (COX-2 specific inhibitor). Since glioblastoma, medulloblastoma, and neuroblastoma tumors show high expression of cyclooxygenase-2 (COX-2) and nonsteroidal anti-inflammatory drugs (NSAIDs) levels, COX-2 and PGE2 inhibitors possess a profound effect on tumor growth. The two inhibitors

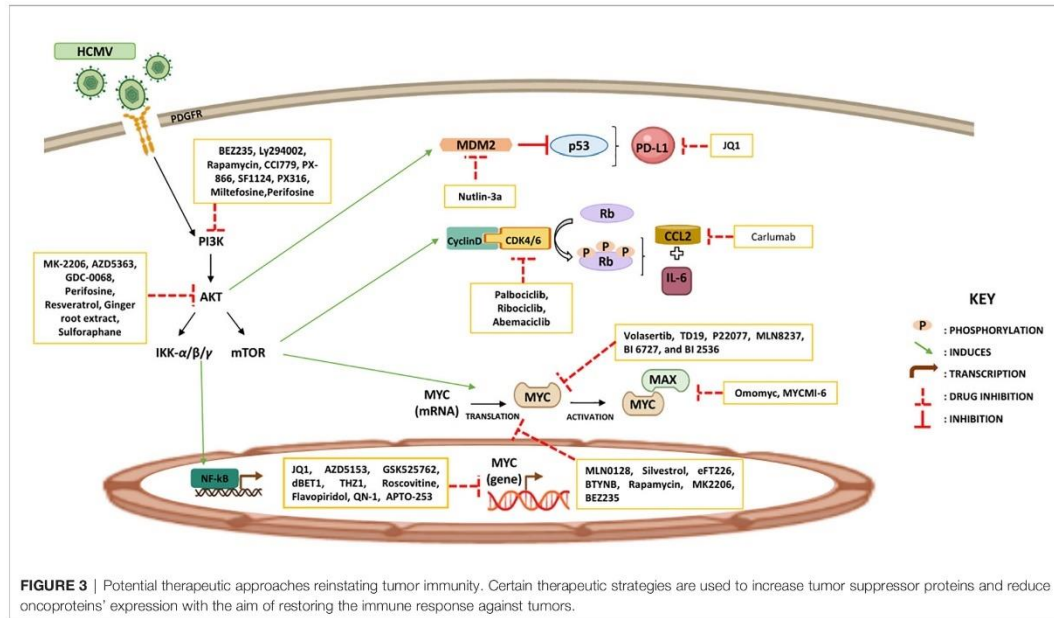

competently block HCMV replication and limiting the US28-expressing tumor cell growth. Therefore, the significant effects behind the use of aspirin and other NSAIDs in tumor prevention investigations could be somewhat due to the suppression of HCMV replication in pre-malignant lesions (80). The existing link between CMV and cancer creates a new avenue for immunotherapeutic strategies that target CMV such as, adoptive T-cell transfer and vaccine approaches (172). During adoptive lymphocyte transfer (ALT), autologous T-cells are expanded and activated *ex vivo* against the tumor. After that, they are transferred into patients where lymphodepletion stimulates a substantial proliferation of T-cells and intensifies tumor-specific immunity (173, 174). There exist various ongoing clinical studies assessing the effectiveness of adoptive T-cell therapy using HCMV-specific T-cells, or DCs with CMV-pp65 RNA in order to vaccinate GBM patients. CMV-specific T-cells, especially pp65-specific T-cells, favorably infiltrate glioblastoma tumors and were able to stimulate glioblastoma cells' killing (173). The fact that a high percentage of GBM samples were HCMV-positive has led to potential immunotherapy targets for GBM treatment. HCMV-specific proteins (IE1, pp65, and gB) are being investigated for the development of immunotherapy targets (116, 174). Interestingly, a study showed that CMV-stimulated NK cells and  $\gamma\delta$ -T-cells might have antineoplastic potential and CMV reactivation has been associated with minimal risk for relapsed leukemia in hematopoietic stem-cell transplantation (HSCT) patients (173). Since oncolytic virotherapy has been recognized as a promising approach for treating cancers in recent years, the use of "oncolytic CMV therapy" in combination with anti-tumor medications, immune checkpoint inhibitors (targeting CTLA4 and PD-L1), epigenetic therapeutics, or as "HCMV/HSV-1 oncolytic virus" could be regarded as one of the most intriguing antitumor approaches (175).

Major approaches used to target Myc are mostly targeting Myc gene transcription (JQ1, AZD5153, GSK525762, dBET1, THZ1, Roscovitine, Flavopiridol, QN-1, and APTO-253), inhibiting Myc mRNA translation (MLN0128, Silvestrol, eFT226, BTYNB, Rapamycin, MK2206, BEZ235), targeting Myc oncoprotein stability (Volasertib, TD19, P22077, MLN8237, BI 6727, and BI 2536), controlling Myc-Max interactions (Omomyc and MYCMI-6), and blocking Myc's accessibility to other genomic targets (Sulfopin) (176–178). Further, bromodomain and extraterminal protein (BET) inhibitor, JQ1, decreased expression of PD-L1 and CD47 resulting in the recruitment of T-cells. Hence, drugs targeting Myc-associated pathways may be used to modify the expression of immune checkpoints (179). Furthermore, the PI3K/AKT pathway is activated in cancer; thus, identifying AKT inhibitors that can block PI3K/AKT signaling could attenuate tumor growth and recover immune responses. AKT inhibitors are classified in Synthetic (MK-2206, AZD5363, GDC-0068, Perifosine) and natural AKT inhibitors (Resveratrol or grape powder, Ginger root extract, Sulforaphane) (180, 181). Few drugs in clinical use or preclinical assessment have been verified to directly or indirectly target PI3K signaling such as BEZ235,

Ly294002, Rapamycin, CCI779, PX-866, SF1124, PX316, Miltefosine, and Perifosine (178, 181). Reactivating tumor suppressors is a substantial pharmacological challenge; restoring p-53 activity stimulated innate immunity particularly DC activation, and it also promoted adaptive immunity. Nutlin-3a, mouse double minute 2 homolog (MDM2) inhibitor, induces local p53 activation in the TME resulting in MDM2-mediated tumor cell apoptosis even in the presence of a sustained Notch activity (168, 182, 183). Re-expression of p53 was stimulated by Tamoxifen injections causing massive apoptosis (179). T-cell responses were driven by using p53 vaccines (ALVAC-p53 and MVAp53) or synthetic long peptides of p53 (169). Moreover, the highly selective cyclin-dependent kinases 4/6 (CDK4/6) inhibitors (Palbociclib, Ribociclib, and Abemaciclib) were proved to avert RB phosphorylation thus regulating MHC presentation, IFN- $\gamma$  response, and IL-6 signaling (184–186). Carlumab, a human IgG1 monoclonal antibody, inhibited CCL2 and it consequently showed promising effects in both solid tumors and metastatic resistant prostate cancer. A distinct approach to CCL2/CCR2 interference, was hindering CCR2 using MLN1202 in bone metastasis (187). It has been shown that CCL2 knockout prompted marked suppression of TAMs-associated inflammatory cytokines (188); in addition, CCL2-CCR2 blockade exhibited tumor-suppressive function by blocking inflammatory monocyte recruitment within the tumor (170) (Figure 3).

Additionally, because of HCMV's ability to establish latency and reactivate, CMV vaccines are presently being developed for clinical use. To prevent HCMV infection in tumor-independent settings, the development of an effective HCMV vaccine has been investigated despite being a struggle for a couple of years. Few have already granted the approval to a phase III clinical trial thus possessing promising outcomes (189). The investigated anti-CMV vaccine types include the live-attenuated (phase 2), recombinant subunit (phase 2), virus vectored phase (1, 2), chimeric peptidic (phase 2), enveloped virus-like particles (phase 1), plasmid-based (phase 3), and mRNA (phase 2) vaccines (190). mRNA-1647, a CMV vaccine covering six mRNAs that encodes pentamer and gB protein, is designed for CMV prophylaxis; a phase 3 study will be initiated to assess the prevention of primary CMV infection in women of childbearing age (ClinicalTrials.gov Identifier: NCT04232280). Recent data showed that HCMV could perhaps induce transformation by enhancing the expression of viral genes (for example, *UL69* gene). The presence of *UL69* gene in CTH cell cultures and *UL69* DNA in the majority of breast cancer biopsies indicates a potential significance of *UL69* as a target in developing HCMV-vaccine (191). The usage of HCMV vaccines for the treatment of cancer patients generally and GBM patients in specific might be of high therapeutic value especially that HCMV has been shown to express oncomodulatory functions. Letemovir, an FDA approved novel terminase inhibitor, is currently used for CMV prophylaxis as it selectively compromises CMV replication. It's characterized by its high potency compared to ganciclovir and limited toxicity profile (192). There exists an ongoing phase 2 clinical trial that aim to assess the anti-inflammatory potential of letemovir in adults with HIV and asymptomatic CMV being on

**FIGURE 3** | Potential therapeutic approaches reinstating tumor immunity. Certain therapeutic strategies are used to increase tumor suppressor proteins and reduce oncoproteins' expression with the aim of restoring the immune response against tumors.

antiretroviral therapy-mediated suppression (ClinicalTrials.gov, Identifier: NCT04840199). Further investigations will be a welcome addition to evaluate the use of letemovir in averting CMV recurrence and treatment as well as to reverse letemovir resistance.

suppress tumor progression. Taking into consideration the profound effects of HCMV on the quality of life, there remain further experimental studies to be performed in order to design effective interventions including vaccines or other approaches that reinforce immune homeostasis and maintain the adapted immune response to aging.

**CONCLUSION**

Overall, HCMV-induced amplification of immune evasion mechanisms mediates oncomodulation and enables tumors to further escape immune surveillance and develop immune tolerance favoring other malignant phenotypes. HCMV, infecting many cell types, induces a pro-inflammatory environment and conquers specific immune responses thus creating an immunosuppressive TME. Nevertheless, getting to know viral immune evasion mechanisms will aid in understanding aspects of cellular as well as immunological function, and contribute to the enhancement of immunotherapies' outcome and antiviral agents eliminating the virus from tumor tissues which could improve patient's immune responses and

## GLOSSARY

ALT	Adoptive lymphocyte transfer
BAK	Bcl-2 homologues antagonist/killer
BAX	BCL2-Associated X Protein
Bcl-2	B-cell lymphoma 2
BET	Bromodomain and extraterminal protein
CDK	Cyclin-dependent kinases
COVID-19	Coronavirus disease 2019
COX-2	Cyclooxygenase-2
CRPs	Complement regulatory proteins
CTH	CMV transformed HMECs
CTLs	Cytotoxic T lymphocytes
DCs	Dendritic cells
DISC	Death-inducing signaling complex
dsDNA	Double-stranded DNA
EBV	Epstein-Barr virus
EMT	Epithelial to mesenchymal transition
EPCR	Endothelial protein C receptor
FAO	Fatty acid oxidation
FLIP	Fas-associated death-domain-like IL-1 $\beta$ -converting enzyme-inhibitory proteins
gB	Glycoproteins B
GBM	Glioblastoma
GCRs	G-Protein-coupled receptors
gH	Glycoprotein H
HCC	Hepatocellular carcinoma
HCMV	Human Cytomegalovirus
HHV-5	Human herpesvirus 5
HLTF	Helicase like transcription factor
HMEC	Human mammary epithelial cells
HSCT	Hematopoietic stem-cell transplantation
IBD	Inflammatory bowel disease
ICAM-1	Intercellular adhesion molecule-1
IFNs	Type I interferons
IL	Interleukin

(Continued)

Continued

IL6R	IL-6 receptor
JAK	Janus kinase
lncRNAs	Long non-coding RNAs
MCP-1	Monocyte chemoattractant protein-1
MCP3	Monocyte chemoattractant protein-3
MDM2	Mouse double minute 2 homolog
MHC	Major histocompatibility complex
MICA	MHC Class I Polypeptide-Related Sequence A
MICB	MHC class I chain-related gene B
MIP-1 $\alpha$	Macrophage inflammatory protein-1 alpha
MIP-1 $\beta$	Macrophage inflammatory protein-1 beta
miRNAs	microRNAs
MS	Mitochondrial superoxide
NK	Natural killer
NKG2D	Natural Killer Group 2D
NOS	Nitric oxide synthase
NSAIDs	Nonsteroidal anti-inflammatory drugs
Oct-4	Octamer-binding transcription factor 4
PBMCs	Peripheral blood mononuclear cells
PDGFR $\alpha$	Platelet-derived growth factor receptor alpha
PD-L1	Programmed death-ligand 1
PI3K/AKT	Phosphatidylinositol-3-kinase and protein kinase B
SLE	Systemic lupus erythematosus
SOX2	SRY-Box Transcription Factor 2
STAT	Signal transducer and activator of transcription
TAMS	Tumor-associated macrophages
Th	T-helper
TLR2	Toll-like receptors 2
TME	Tumor microenvironment
TNFR	Tumor necrosis factor receptor
TNF- $\alpha$	Tumor necrosis factor-alpha
TUSC3	Tumor suppressor candidate 3
UL	Unique long
ULBPs	UL16 binding proteins
US	Unique short
VEGF	Vascular endothelial growth factor
viCA	Viral inhibitor of caspase-8-induced apoptosis
$\gamma\delta$ T-cells	Gamma-delta T-cells

Haidar Ahmad S, Pasquereau S, **El Baba R**, Nehme Z, Lewandowski C, Herbein G. Distinct Oncogenic Transcriptomes in Human Mammary Epithelial Cells Infected With Cytomegalovirus. *Front Immunol* 2021;12:772160. <https://doi.org/10.3389/fimmu.2021.772160>.

Human cytomegalovirus (HCMV) is increasingly recognized as a potential oncovirus, beyond its oncomodulatory role. The study isolated two high-risk HCMV strains, HCMV-DB and HCMV-BL, which promoted oncogenic pathways and tumorigenicity in human mammary epithelial cells. In contrast, low-risk strains like HCMV-FS, KM, and SC did not induce these traits. When comparing high-risk and low-risk strains, high-risk HCMV-BL exhibited numerous pro-oncogenic features, including enhanced expression of oncogenes and genes associated with cell survival, proliferation, and epithelial-mesenchymal transition. Furthermore, mammosphere formation was observed only with high-risk strains. The Ki67 gene proved useful for distinguishing between high-risk and low-risk strains in vitro and in HCMV-positive breast cancer biopsies, primarily in basal tumors, potentially associated with high-risk HCMV strains. Overall, the transcriptome of human mammary epithelial cells infected with HCMV clinical isolates demonstrates an "oncogenic gradient," with high-risk strains creating a pro-oncogenic environment that may contribute to breast cancer development.

Human cytomegalovirus is being recognized as a potential oncovirus beside its oncomodulation role. We previously isolated two clinical isolates, HCMV-DB (KT959235) and HCMV-BL (MW980585), which in primary human mammary epithelial cells promoted oncogenic molecular pathways, established anchorage-independent growth *in vitro*, and produced tumorigenicity in mice models, therefore named high-risk oncogenic strains. In contrast, other clinical HCMV strains such as HCMV-FS, KM, and SC did not trigger such traits, therefore named low-risk oncogenic strains. In this study, we compared high-risk oncogenic HCMV-DB and BL strains (high-risk) with low-risk oncogenic strains HCMV-FS, KM, and SC (low-risk) additionally to the prototypic HCMV-TB40/E, knowing that all strains infect HMECs *in vitro*. Numerous pro-oncogenic features including enhanced expression of oncogenes, cell survival, proliferation, and epithelial-mesenchymal transition genes were observed with HCMV-BL. *In vitro*, mammosphere formation was observed only in high-risk strains. HCMV-TB40/E showed an intermediate transcriptome landscape with limited mammosphere formation. Since we observed that Ki67 gene expression allows us to discriminate between high and low-risk HCMV strains *in vitro*, we further tested its expression *in vivo*. Among HCMV-positive breast cancer biopsies, we only detected high expression of the Ki67 gene in basal tumors which may correspond to the presence of high-risk HCMV strains within tumors. Altogether, the transcriptome of HMECs infected with HCMV clinical isolates displays an “oncogenic gradient” where high-risk strains specifically induce a prooncogenic environment which might participate in breast cancer development.

**Keywords:** HCMV, cytomegalovirus, oncogenesis, breast cancer, high-risk, low-risk

## INTRODUCTION

Breast cancer is the most common cancer diagnosed among women and recognized as one of the main causes of death in women (1). Etiologic factors of breast cancer are classified into genetic and environmental risk factors (2), and among these latter viruses could be involved (3, 4). Furthermore, the DNA and gene products of several viruses have been identified in breast cancer biopsies (5). Human cytomegalovirus (HCMV), a ubiquitous pathogen belonging to the *Herpesviridae* family,

has been detected in 90% of early and metastatic breast cancers (6–8). Likewise, HCMV DNA or antigens have been found in other malignancies including brain (glioblastoma, medulloblastoma), colon, prostate, and liver (7, 9–13). HCMV causes asymptomatic to mild infection in immunocompetent host, but it can lead to serious complications in the immunocompromised host and cancer patients (14, 15).

Although the growth of laboratory HCMV strains is restricted to fibroblasts, the clinical HCMV isolates infect a broad range of cells including epithelial cells, endothelial cells, monocytes, macrophages, fibroblasts, stromal cells, hepatocytes, smooth muscle cells, and neural stem/progenitor cells (16–19). Despite its known onco- and immunomodulatory effects, HCMV can transform primary human mammary epithelial cells (HMECs) *in vitro* as previously reported for the HCMV-DB and HCMV-BL strains (20, 21) in addition to the human embryonal lung fibroblasts (22). Moreover, blood monocyte, tissue macrophages, CD34+, and neural stem/progenitor are identified as HCMV reservoirs harboring latent virus (17, 23–28).

The different oncogenic abilities, cellular and molecular characteristics allowed us to classify HCMV strains into high or low-risk oncogenic strains. The high-risk strains promoted oncogenic molecular pathways, induced the expression of stemness markers, transformed epithelial cells, induced the appearance of polyploid giant cancer cells (PGCCs) in culture, established anchorage-independent growth *in vitro*, and produced tumorigenicity in mice models (20, 21). In contrast, the low-risk strains did not display such oncogenic features (21).

Herein, we compared six clinical HCMV strains for their oncogenic potential in HMECs using soft agar assay and transcriptomic analysis. Therefore, we compared the transcriptome profile of HMECs infected with the high-risk HCMV-BL strain versus the low-risk HCMV-FS, KM and SC strains. The transcriptome of HMECs infected with HCMV-BL presents oncogenic traits, favors cell cycling, cell proliferation, and epithelial-to-mesenchymal transition (EMT). However, the transcriptome of the HCMV-FS, KM and SC low-risk strains did not show any of the previously mentioned characteristics. HMECs infected with HCMV-TB40/E displayed a transcriptome phenotype similar to that of the HCMV-FS low-risk strain. In agreement with these distinct transcriptome profiles observed, we noticed the highest transformation and mammosphere formation in HMECs infected with the HCMV-BL high-risk strain, but not with the HCMV-FS, HCMV-KM and HCMV-SC low-risk ones. In line with the transcriptome phenotype observed in acutely infected HMECs, we perceived the preferential detection of high-risk HCMV strains along with the high expression of Ki67 in breast cancer biopsies, especially in the basal-like ones.

## MATERIALS AND METHODS

### Cell Cultures

HMECs were purchased from Life Technologies (Carlsbad, CA, USA). MDA-MB231 and MCF7 cells were provided by Institut Hiscia (Arllesheim, Switzerland). Human embryonal lung

fibroblasts (MRC5) were purchased from RD-Biotech (Besançon, France). HMECs were cultivated in HMEC medium (Life Technologies) supplemented with HMEC supplement and bovine pituitary extract (Life Technologies). MDA-MB231, MCF7, and MRC5 were maintained in Dulbecco's modified Eagle medium (PAN-Biotech) supplemented with fetal bovine serum (Dutscher) and penicillin-streptomycin (Life Technologies). Cultures were free of mycoplasma (VenorGem classic mycoplasma detection, Minerva biolabs).

### HMECs Infection With HCMV

HMECs were infected with HCMV-DB (KT959235), HCMV-BL (MW980585), HCMV-TB40/E (KF297339), HCMV-FS, HCMV-KM, and HCMV-SC. The HCMV clinical isolates were previously isolated in our laboratory (20, 21), except for HCMV-TB40/E (29). Cell-free virus stocks of HCMV were grown in HMECs as described previously (21). Virus titers were determined through the quantification of HCMV load by real-time qPCR detection using KAPA SYBR FAST Master Mix, Omega Bio-TEK) and *IE1* gene primers (sense, 5'-CGACGT TCCTGCAGACTATG-3'; anti-sense, 5'-TCCTCGGTCA CTTGTTCAAA-3') according to the manufacturer's protocol. Results were collected and analyzed using MxPro qPCR software.

### Soft Agar Colony Formation Assay

Colony formation in soft agar seeded with HMECs uninfected, infected with the six strains listed above, MCF7 cells and MDA-MB231 cells were assayed using Cell Biolabs Cytosolic Cell Transformation Assay kit (Colorimetric assay, CB135; Cell Biolabs Inc., San Diego, CA) as per the manufacturer's protocol. The detection and quantification of colony formation was assessed by MTT assay (Cayman Chemical, Ann Arbor, MI). Colonies were observed under an Olympus microscope (Olympus Corporation, Tokyo, Japan).

### Confocal Microscopy and Immunohistochemistry

Confocal microscopy was performed as described previously (21). Cells were washed using 1X PBS then fixed and permeabilized using BD Cytotfix/Cytoperm, and finally stained with anti-IE1 (pp72) antibody (ab53495, Abcam). To visualize the nucleus, DAPI (4', 6'-diamidino-2-phenylindole) staining was performed according to the manufacturer's protocol. Post-staining, confocal images were taken using 63X oil immersion objective lens with a LSM800 Carl-Zeiss confocal microscope 95 (Germany). The Ki67 immunohistochemistry (IHC) evaluation on breast biopsies was assessed using the monoclonal antibody MIB1 (Invitrogen).

### Flow Cytometry Analysis

Uninfected HMECs and HCMV-infected HMECs were fixed and permeabilized for 20 minutes at 4°C using 100 µl Cytotfix/Cytoperm solution (BD Biosciences), washed twice with 1X PBS supplemented with 3% FBS and 0.1% Triton-X, and then re-suspended in 100ul of staining buffer (1X PBS, 3% FBS, and

0.1% Triton-X). Cell staining was done using the anti-IE1 (CMV-pp72) antibody conjugated to PE (sc-69834, Santa Cruz Biotechnology). HMECs were incubated in the dark for 60 minutes at 4°C. Cells were washed twice with 1X PBS supplemented with 3% FBS and 0.1% Triton-X and subjected to cytofluorometric analysis on a BD LSRFortessa X-20 (BD Biosciences) flow cytometer. Data obtained was analyzed and processed using FACSDiva software (BD Biosciences).

### Phylogenetic Analysis

Phylogenetic analysis was performed on several HCMV strains [BL (accession number: MW980585); DB (accession number: KT959235); TB40/E (accession number: KF297339); and Davis (accession number: JX512198.1)]. Multi-sequence alignments (MSA) were implemented using CLUSTAL W. Phylogenetic tree was constructed by means of the neighbor-joining method. The conducted analysis was done using MEGA7 software (<http://www.megasoftware.net/>).

### RT<sup>2</sup> Profiler™ PCR Arrays Experiment

Total RNA was extracted from uninfected HMECs and HMECs infected with HCMV-BL, HCMV-TB40/E, HCMV-FS, HCMV-KM and HCMV-SC at MOI of 1 at day 1 post-infection using an RNA extraction kit (EZNA Total kit I, Omega BIO-TEK). Then, the cDNA was synthesized using the RT<sup>2</sup> First Strand Kit (Qiagen, Germantown, MD, USA) following the manufacturer's instructions. Two RT<sup>2</sup> Profiler™ PCR Arrays for human breast cancer (PAHS-131ZA) and human oncogenes & tumor suppressor genes (PAHS-502ZR) (both from Qiagen, Germantown, MD, USA) were performed using Mx3005P real-time PCR system as per manufacturer's instructions. These microarrays allow the quantification of mRNA from 84 cellular genes, using qPCR with premixed primer sets and SybrGreen qPCR MasterMix. DNA contamination control, housekeeping genes, reverse transcription control, and positive control were included in each PCR array. Data were analyzed using the manufacturer web-based analysis software (<http://pcrdataanalysis.sabiosciences.com/pcr/arrayanalysis.php>). The analysis was done based on three independent biological experiments for each of the HCMV strains.

### Mammosphere Assay

Mammosphere formation by uninfected HMECs and HMECs infected with HCMV-BL, HCMV-TB40/E, HCMV-FS, and HCMV-KM at MOI of 1 was assayed as described previously (19). MCF7 and MDA-MB231 were used as positive controls. Mammospheres larger than 60 microns were counted.

### Western Blotting

Cellular extracts of uninfected and infected HMECs with HCMV-DB and HCMV-TB40/E were prepared at 1 hour, 5 hours, days 1 and 3 post-infection and used to assess the expression of Rb, pRb, Akt, pAkt-Th308, pAkt-Ser473, STAT3, pSTAT3, CyclinD1, and ATM as described previously (20). Protein levels were quantified using ImageJ 1.40 software (National Institutes of Health, Bethesda, MA, USA).  $\beta$ -actin was used as loading control to normalize sample loading.

Anti-Rb, anti-pRb, anti-Akt, anti-pAktThr308, anti-pAktSer473, anti-cyclin D1, and anti-ATM antibodies were purchased from Cell signaling (Danvers, MA, USA). Anti-pSTAT3 and anti-STAT3 antibodies were purchased from Santa Cruz Biotechnology (Santa Cruz, CA). Anti- $\beta$ -actin antibody was purchased from Sigma-Aldrich (St. Louis, MO, USA).

### Breast Biopsies

Nineteen frozen tumor breast biopsies (ten luminal tumor biopsies and nine basal tumor biopsies) and eight adjacent healthy breast biopsies were provided by the regional tumor bank (BB0033-00024 Tumorothèque Régionale de Franche-Comté). Healthy breast biopsies were numbered from one to eight, luminal tumor biopsies from nine to eighteen, and basal tumor biopsies from nineteen to twenty-seven. A detailed histopathological biopsy data including the histologic biopsy type, Elston-Ellis grading system, hormone percentages (estrogen and progesterone), presence or absence of the human epidermal growth factor receptor 2 (HER2) protein, vascular emboli, and TNM staging was provided as a supplementary data (**Supplementary Table 1**). Additionally, using twenty different breast tumor biopsies, we assessed the Ki67 mRNA and Ki67 protein levels measured by RT-qPCR and IHC, respectively, on the same biopsy sample. A written informed consent for participation was obtained from all patients. The study was authorized by the local ethics committees of Besançon University Hospital (Besançon, France) and the French Research Ministry (AC-2015-2496, CNIL n°1173545, NF-S-138 96900 n°F2015). The presence of HCMV, within all the biopsies, was assessed by qPCR using IE1 and UL69 primers as mentioned above and described previously (30). For Ki67 and GAPDH mRNA quantification, RNA was extracted from the biopsies using E.Z.N.A.® Total RNA Kit I (Omega BIO-TEK, GA, USA). Reverse transcription was performed using the SuperScript IV First-Strand Synthesis kit (Invitrogen, Carlsbad, CA, USA). The expression of Ki67 and GAPDH was assessed by real-time qPCR using KAPA SYBR FAST Master mix (KAPA BIOSYSTEMS, KK4601) and specific primer for Ki67 (sense, 5'TCCTTTGGTGGGCACCTAA GACCTG3'; anti-sense, 5'TGATGGTTGAGGTCGTTTCCTTG ATG3') and GAPDH (sense, 5'CCCCTCTTCAAGGCCTC TAC3'; anti-sense, 5'CGACCACTTTGTCAAGCTCA3') according to the manufacturer's protocol. The fold change expression was calculated using the delta-delta Ct method (31). Biopsies having a fold change for Ki67 gene expression <30, from 30 to 100, and >100 were considered to have a low, intermediate, and high Ki67 mRNA absolute level respectively. The Ki67 mRNA cut-off was set based on the state of healthy biopsies (32).

### Statistical Analysis

Statistical analysis was performed using the Wilcoxon test with the help of the Mathematics Department of the University of Franche-Comté. *p*-value  $\leq 0.05$  were considered statistically significant. In data analysis, Microsoft Excel was used to prepare the plots with

standard deviation and p-values. Statistical significance was represented on figures by stars, with the following code \* $p$ -value<0.05; \*\* $p$ -value<0.01; \*\*\* $p$ -value<0.001.

## RESULTS

### Growth and Transforming Capacity of Six HCMV Clinical Strains in HMECs

A phylogenetic analysis was performed to analyse the genomic sequences of four HCMV strains, namely HCMV-DB, HCMV-BL, HCMV-TB40/E, and HCMV-Davis. Since the clinical isolates FS, KM and SC genomes were not sequenced, we selected the strain Davis for its similar clinical characteristics (33). The phylogenetic analysis showed that HCMV-BL is close to HCMV-DB, and HCMV-TB40/E is close to the genomes of HCMV-Davis (**Supplementary Figure 1**). The two observable brackets illustrate a high-risk group including DB and BL strains, and a low-risk group including TB40/E and Davis strains (**Supplementary Figure 1**).

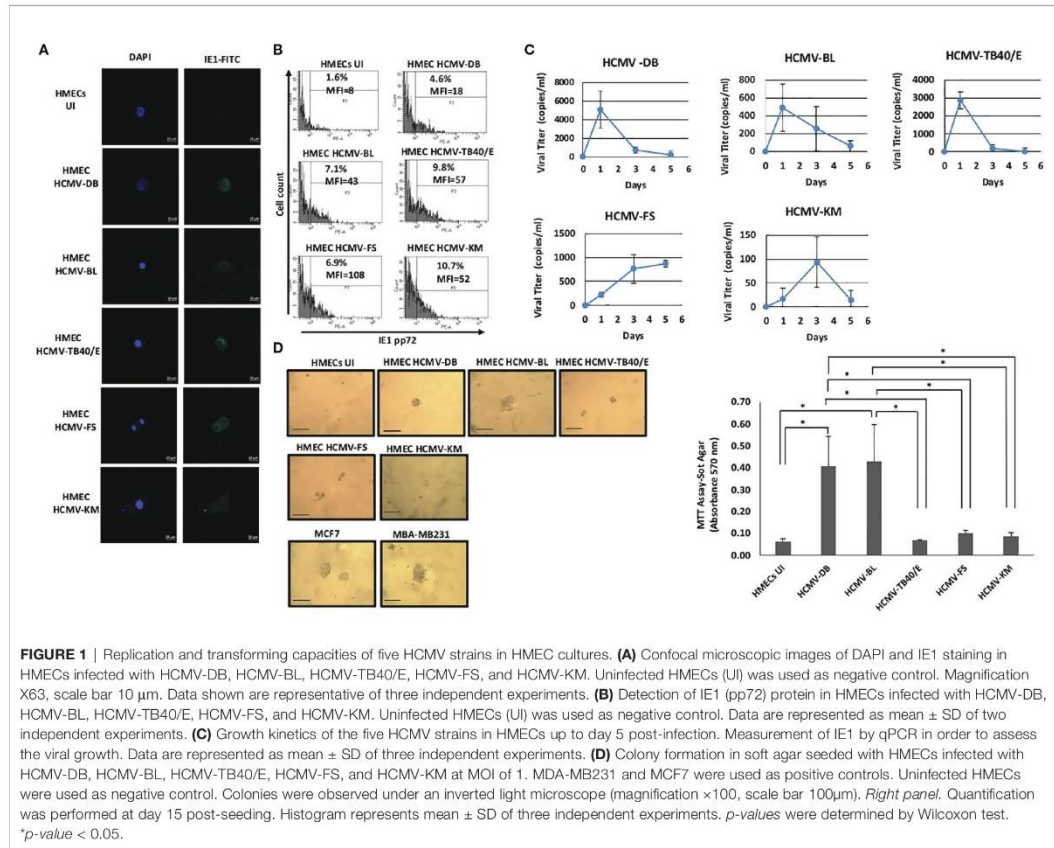

We assessed the replication of six HCMV clinical isolates in HMECs, namely the HCMV-BL and HCMV-DB high-risk strains, the HCMV-FS, HCMV-KM and HCMV-SC low-risk strains, and the prototypic TB40/E strain (20, 21, 29). We evaluated the expression of the immediate early protein IE1 by immunofluorescence and flow cytometry. We observed strong IE1 expression in HMECs infected with the five strains (HCMV-DB, BL, TB40/E, FS and KM) at day 1 post-infection compared to the uninfected HMECs by confocal microscopy (**Figure 1A**). Moreover, the expression of IE1 protein in HMECs infected with the different HCMV strains was confirmed by flow cytometric analysis (**Figure 1B**). Further, we noticed productive replication of all six HCMV strains in infected HMECs as assayed by IE1 detection in culture supernatants using qPCR (**Figure 1C** and **Supplementary Figure 2A**). An early and transient peak of viral replication was observed at day 1 post-infection for HMECs infected with HCMV-DB, HCMV-BL, and HCMV-TB40/E unlike the delayed peaks at day 3 and 5 post-infection for HMECs infected with HCMV-KM and HCMV-FS respectively. To further assess the oncogenic status of all six HCMV strains, we performed a soft agar assay. HMECs infected with the six HCMV strains were seeded in soft agar at day 1 post-infection. Cancer cell lines, MCF7 and MDA-MB231, were used as positive controls. Uninfected HMECs were used as negative control. Colony formation was detected at day 15 post-infection only with HCMV-DB and HCMV-BL compared to the uninfected HMECs ( $p$ -value<sub>(HCMV-DB : UI HMEC)</sub> = 0.03,  $p$ -value<sub>(HCMV-BL : UI HMEC)</sub> = 0.03,  $p$ -value<sub>(HCMV-DB : HCMV-TB40/E)</sub> = 0.03;  $p$ -value<sub>(HCMV-DB : HCMV-FS)</sub> = 0.03;  $p$ -value<sub>(HCMV-DB : HCMV-KM)</sub> = 0.03;  $p$ -value<sub>(HCMV-BL : HCMV-TB40/E)</sub> = 0.03;  $p$ -value<sub>(HCMV-BL : HCMV-FS)</sub> = 0.03;  $p$ -value<sub>(HCMV-BL : HCMV-KM)</sub> = 0.03). In contrast, no significant colony formation was observed with HCMV-FS, HCMV-KM, HCMV-SC, and HCMV-TB40/E infected HMECs (**Figure 1D** and **Supplementary Figure 2B**). Our results indicate that HMECs infected with the high-risk strains BL and DB have an anchorage-independent growth ability.

### Distinct Transcriptome Profiles in HMECs Infected With Low-Risk and High-Risk HCMV Strains

We decided to compare the transcriptome profile of the high-risk BL strain, the low-risk FS, KM and SC strains, and the prototypic TB40/E strain. Human breast cancer along with human oncogenes and tumor suppressor genes RT<sup>2</sup> profiler PCR arrays were used to screen the infected HMECs with the four strains at MOI of 1 at day 1 post-infection and the uninfected HMECs. The expression of genes that are involved in signal transduction, cell cycle, cell survival, adhesion, angiogenesis, DNA repair, were examined by the RT<sup>2</sup> Profiler PCR arrays (**Supplementary Tables 2, 3**).

The individual gene expression of the oncogenes *Myc* (MYC), *Fos* (FOS), *Jun* (JUN), *KRas* (KRAS), and *E2F1* was assessed in HMECs infected with the five strains HCMV-BL, TB40/E, FS, KM and SC compared to uninfected HMECs (**Figures 2A, 3A** and **Supplementary Figure 2C**). Values for individual genes were pooled to constitute the overall expression of the oncogenes group (**Figure 2A**). In HMECs infected with HCMV-BL, the expression of the oncogenes group was 5.8-fold higher compared to HMECs infected with the TB40/E strain ( $p$ -value<sub>(HCMV-BL : HCMV-TB40/E)</sub> = 0.02), 8.5-fold higher compared to HMECs infected with FS strain ( $p$ -value<sub>(HCMV-BL : HCMV-FS)</sub> = 0.004) (**Figure 2A**). However, the expression of these oncogenes was downregulated in HMECs infected with the KM strain ( $p$ -value<sub>(HCMV-BL : HCMV-KM)</sub> = 0.0001) (**Figure 2A**). Among the oncogenes, *Myc* and *E2F1* were mostly increased in HMECs infected with HCMV-BL compared to HCMV-TB40/E ( $p$ -value<sub>(Myc : HCMV-BL : HCMV-TB40/E)</sub> = 0.12;  $p$ -value<sub>(E2F1 : HCMV-BL : HCMV-TB40/E)</sub> = 0.04), HCMV-FS ( $p$ -value<sub>(Myc : HCMV-BL : HCMV-FS)</sub> = 0.12;  $p$ -value<sub>(E2F1 : HCMV-BL : HCMV-FS)</sub> = 0.27) and HCMV-KM ( $p$ -value<sub>(Myc : HCMV-BL : HCMV-KM)</sub> = 0.04;  $p$ -value<sub>(E2F1 : HCMV-BL : HCMV-KM)</sub> = 0.12) infected HMECs (**Figure 3A**). Furthermore, the expression of other oncogenes was tested for HMECs infected with the high-risk strain BL and the low-risk strain FS versus uninfected HMECs. We observed an upregulation of the transcripts of numerous other oncogenes such as *KITLG*, *MYB*, *RARA*, *ROS1*, and *RUNX1* in HMECs infected with HCMV-BL and HCMV-FS (**Table 1**). The upregulation of *KITLG*, *RARA*, and *ROS1* genes expression was at least 2-fold higher in HMECs infected with HCMV-BL compared to HMECs infected with HCMV-FS (**Table 1**). In HMECs infected with HCMV-SC, the oncogenes' expression (*MYC*, *FOS*, *KRAS*, *JUN*, *E2F1*) was low, likewise in HMECs infected with HCMV-FS (**Supplementary Figure 2C**).

The individual gene expression of the tumor suppressor genes coding for p53 protein (TP53), retinoblastoma protein (Rb), p73 protein (TP73), SMAD4, VHL, TSC1, and MDM2 was also assessed in the previously mentioned five strains compared to uninfected HMECs (**Figures 2B, 3B** and **Supplementary Figure 2C**). Values for individual genes were pooled to constitute the overall expression of the tumor suppressor genes group (**Figure 2B**). The upregulation of tumor suppressor genes' expression was higher in HMECs infected with the BL strain compared to HMECs infected with the TB40/E and FS by 2

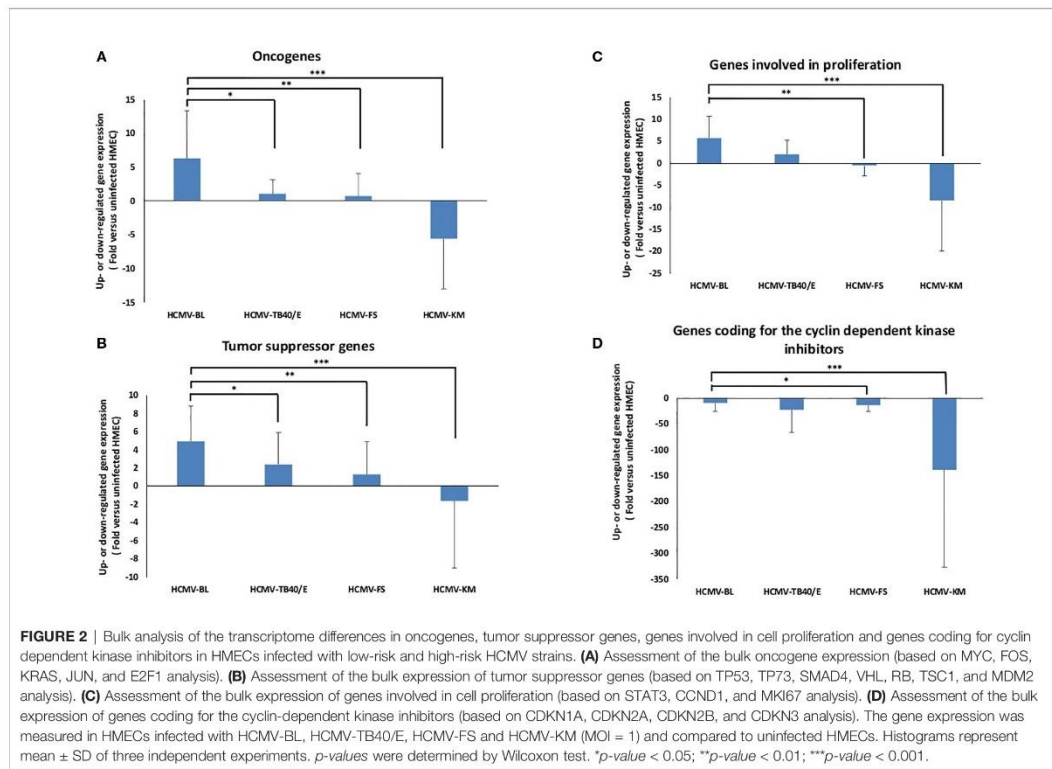

**FIGURE 1 |** Replication and transforming capacities of five HCMV strains in HMEC cultures. **(A)** Confocal microscopic images of DAPI and IE1 staining in HMECs infected with HCMV-DB, HCMV-BL, HCMV-TB40/E, HCMV-FS, and HCMV-KM. Uninfected HMECs (UI) was used as negative control. Magnification X63, scale bar 10  $\mu$ m. Data shown are representative of three independent experiments. **(B)** Detection of IE1 (pp72) protein in HMECs infected with HCMV-DB, HCMV-BL, HCMV-TB40/E, HCMV-FS, and HCMV-KM. Uninfected HMECs (UI) was used as negative control. Data are represented as mean  $\pm$  SD of two independent experiments. **(C)** Growth kinetics of the five HCMV strains in HMECs up to day 5 post-infection. Measurement of IE1 by qPCR in order to assess the viral growth. Data are represented as mean  $\pm$  SD of three independent experiments. **(D)** Colony formation in soft agar seeded with HMECs infected with HCMV-DB, HCMV-BL, HCMV-TB40/E, HCMV-FS, and HCMV-KM at MOI of 1. MDA-MB231 and MCF7 were used as positive controls. Uninfected HMECs were used as negative control. Colonies were observed under an inverted light microscope (magnification  $\times$ 100, scale bar 100 $\mu$ m). *Right panel.* Quantification was performed at day 15 post-seeding. Histogram represents mean  $\pm$  SD of three independent experiments. *p-values* were determined by Wilcoxon test. \**p-value* < 0.05.

(*p-value* (HCMV-BL: HCMV-TB40/E) = 0.02) and 3.8 fold (*p-value* (HCMV-BL: HCMV-FS) = 0.002) respectively (Figures 2B). Nevertheless, the expression of these tumor suppressor genes was downregulated in HMECs infected with HCMV-KM (*p-value* (HCMV-BL: HCMV-KM) = 0.00001) (Figure 2B). Among the tumor suppressor genes, TP53, VHL, Rb, and TSC1 expression was mainly increased in HMECs infected with HCMV-BL compared to HCMV-TB40/E (*p-value* (TP53- HCMV-BL: HCMV-TB40/E) = 0.04; *p-value* (SMAD4- HCMV-BL: HCMV-TB40/E) = 0.82; *p-value* (VHL- HCMV-BL: HCMV-TB40/E) = 0.27; *p-value* (Rb- HCMV-BL: HCMV-TB40/E) = 0.04; *p-value* (TSC1- HCMV-BL: HCMV-TB40/E) = 0.51), HCMV-FS (*p-value* (TP53- HCMV-BL: HCMV-FS) = 0.04; *p-value* (SMAD4- HCMV-BL: HCMV-FS) = 0.12; *p-value* (VHL- HCMV-BL: HCMV-FS) = 0.51; *p-value* (Rb- HCMV-BL: HCMV-FS) = 0.04; *p-value* (TSC1- HCMV-BL: HCMV-FS) = 0.51), and HCMV-KM (*p-value* (TP53- HCMV-BL: HCMV-KM) = 0.04; *p-value* (SMAD4- HCMV-BL: HCMV-KM) = 0.04; *p-value* (VHL- HCMV-BL: HCMV-KM) = 0.12; *p-value* (Rb- HCMV-BL: HCMV-KM) = 0.04; *p-value* (TSC1- HCMV-BL: HCMV-KM) = 0.12) (Figure 3B). In HMECs infected with HCMV-SC, the tumor suppressor genes (TP53, VHL, TSC1) were slightly expressed,

similarly in HMECs infected with HCMV-FS (Supplementary Figure 2C). The expression of TP73, a tumor suppressor gene, was markedly increased in HMECs infected with low-risk HCMV strains (KM and SC) and to a lower extent with FS and TB40/E strains compared to HMECs infected with high-risk BL strain (Figure 3B and Supplementary Figure 2C).

We then analyzed the individual expression of genes involved in cell proliferation namely STAT3, cyclin D1 (CCND1), and Ki67 antigen (MKI67). Interestingly, the STAT3/Cyclin D1 axis is activated in several cancer types including breast cancer (34). Values for individual genes were pooled to constitute the overall expression of the genes involved in cell proliferation group (Figure 2C). The expression of “proliferation” genes all together was 2.81 times more upregulated in the HMECs infected with the BL strain compared to HMECs infected with the TB40/E strain (*p-value* (HCMV-BL: HCMV-TB40/E) = 0.05) (Figure 2C). While the expression of “proliferation” genes was almost unchanged in HMECs infected with HCMV-FS compared to uninfected HMECs (*p-value* (HCMV-BL: HCMV-FS) = 0.005), it was downregulated in HMECs infected with HCMV-

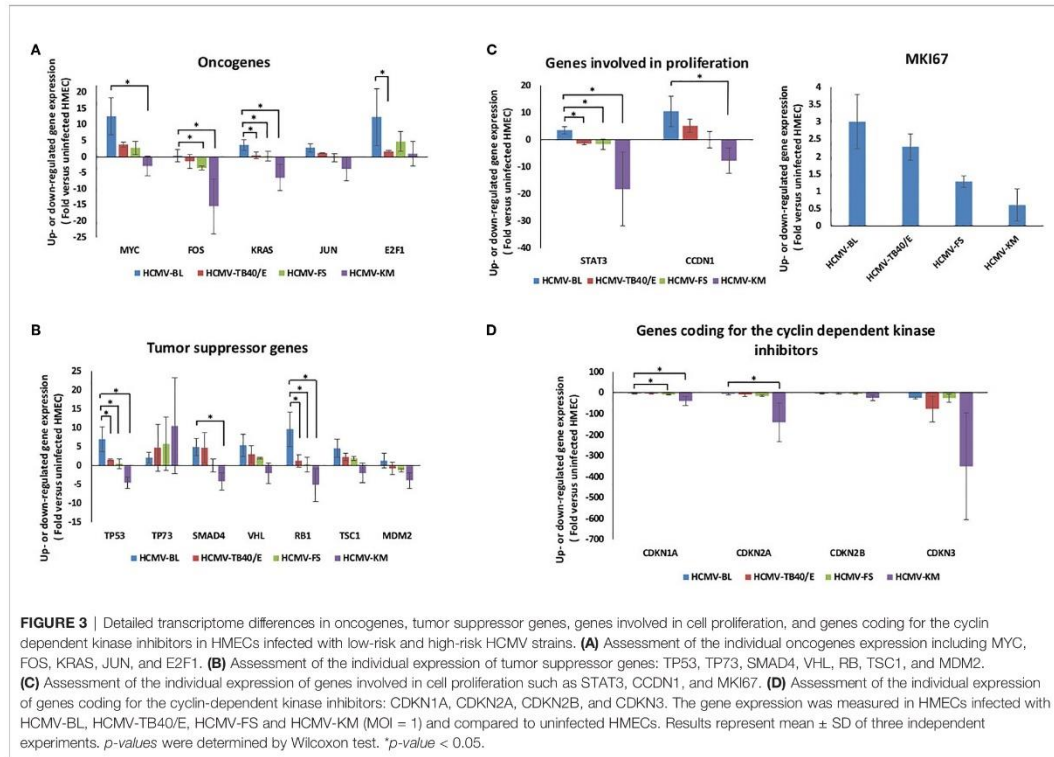

KM (*p*-value (HCMV-BL: HCMV-KM) = 0.0007) (Figure 2C). The *STAT3* gene expression was up-regulated in HMECs infected with HCMV-BL in contrast to HMECs infected with HCMV-TB40/E (*p*-value (HCMV-BL: HCMV-TB40/E) = 0.04) and HCMV-FS (*p*-value (HCMV-BL: HCMV-FS) = 0.04) noting that it was substantially down-regulated in HMECs infected with HCMV-KM (*p*-value (HCMV-BL: HCMV-KM) = 0.04) (Figure 3C). The gene expression of cyclin D1 was up-regulated in HMECs infected with HCMV-BL compared to uninfected controls. In HMECs infected with HCMV-BL, cyclin D1 gene expression was 2 times more increased when compared to HMECs infected with HCMV-TB40/E (*p*-value (HCMV-BL: HCMV-TB40/E) = 0.12). In contrast, the expression of cyclin D1 was almost unchanged in HMECs infected with HCMV-FS compared to uninfected HMECs (*p*-value (HCMV-BL: HCMV-FS) = 0.12), and down-regulated with in HMECs infected with HCMV-KM (*p*-value (HCMV-BL: HCMV-KM) = 0.04) (Figure 3C). In agreement with the highest expression of cyclin D1 in HMECs infected with HCMV-BL and the lowest expression in HMECs infected with HCMV-KM strain, we observed the highest expression of the proliferation marker Ki67 gene (MKI67) in the former and very low expression in the latter (3-fold versus 0.6-fold increase compared to uninfected cells) (Figure 3C). HMECs infected with HCMV-SC showed a low expression of the genes

involved in proliferation (CCDN1, MKI67) likewise in HMECs infected with the low-risk strains (Supplementary Figure 2C). We also assessed the expression of CDK inhibitors CDKN1A, CDKN2A, CDKN2B and CDKN3. Values for individual genes were pooled to constitute the overall expression of CDK inhibitors group (Figure 2D). The expression of CDK inhibitors genes was slightly decreased in HMECs infected with HCMV-BL compared to the other three strains TB40/E (*p*-value (HCMV-BL: HCMV-TB40/E) = 0.81), FS (*p*-value (HCMV-BL: HCMV-FS) = 0.02) and KM (*p*-value (HCMV-BL: HCMV-KM) = 0.001) (Figures 2D, 3D). HMECs infected with HCMV-SC showed a minimal expression of the genes coding for the cyclin dependent kinase inhibitors (Supplementary Figure 2C).

### HMECs Infected With Low-Risk and High-Risk HCMV Clinical Strains Display Distinct Expression of Cell Survival, Cell Adhesion, Angiogenesis, and EMT Genes

The expression of genes involved in cell survival, such as *AKT*, was upregulated in HMECs infected with BL, and TB40/E strains unlike in HMECs infected with FS and KM strains (*p*-value (HCMV-BL: HCMV-FS) = 0.12 and *p*-value (HCMV-BL: HCMV-KM) = 0.04) (Figure 4A). In addition, *REL* was upregulated more in

**FIGURE 3** | Detailed transcriptome differences in oncogenes, tumor suppressor genes, genes involved in cell proliferation, and genes coding for the cyclin dependent kinase inhibitors in HMECs infected with low-risk and high-risk HCMV strains. **(A)** Assessment of the individual expression including MYC, FOS, KRAS, JUN, and E2F1. **(B)** Assessment of the individual expression of tumor suppressor genes: TP53, TP73, SMAD4, VHL, RB, TSC1, and MDM2. **(C)** Assessment of the individual expression of genes involved in cell proliferation such as STAT3, CCN1, and MKI67. **(D)** Assessment of the individual expression of genes coding for the cyclin-dependent kinase inhibitors: CDKN1A, CDKN2A, CDKN2B, and CDKN3. The gene expression was measured in HMECs infected with HCMV-BL, HCMV-TB40/E, HCMV-FS and HCMV-KM (MOI = 1) and compared to uninfected HMECs. Results represent mean  $\pm$  SD of three independent experiments. *p*-values were determined by Wilcoxon test. \**p*-value < 0.05.

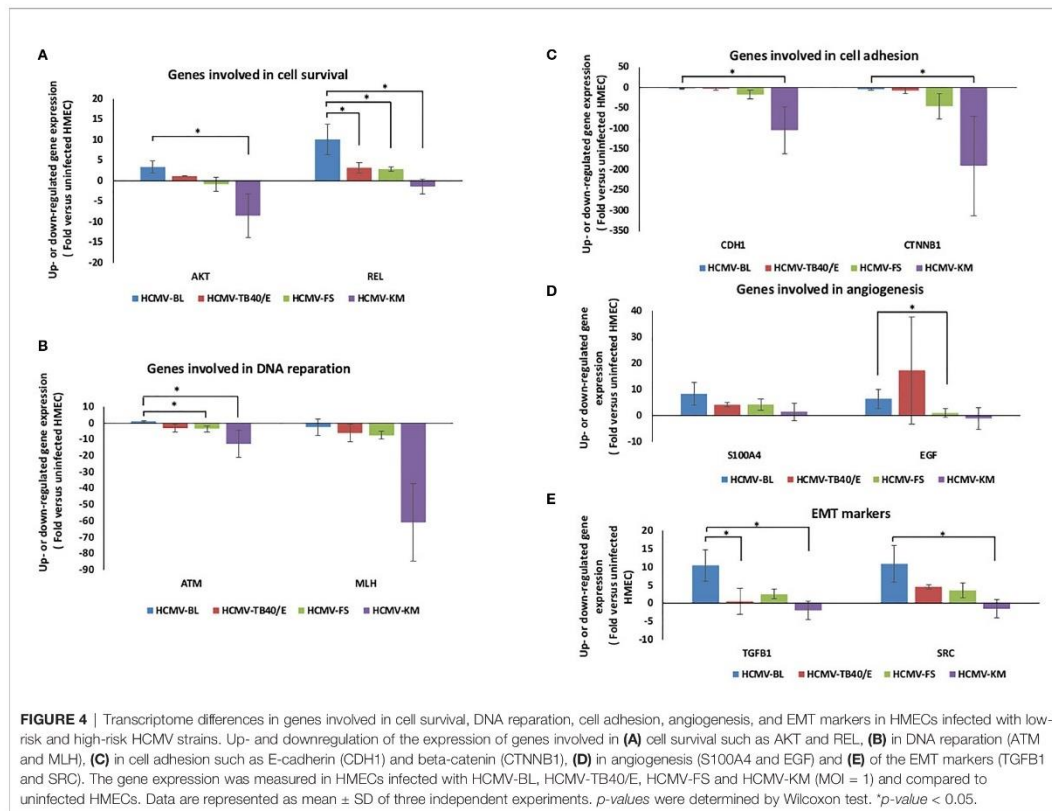

**TABLE 1** | The fold change of several oncogenes' expression in HMECs infected with HCMV-BL and HCMV-FS versus uninfected HMECs.

Gene expression in HMECs infected with(Fold versus uninfected HMECs)		
Gene	HCMV-BL	HCMV-FS
KITLG	5.04*	1.93
MYB	11.10	6.15
RARA	74.67*	36.28
ROS1	29.50*	14.04
RUNX1	3.49	2.45

\*Upregulated gene expression at least two times more in HMEC infected with HCMV-BL compared to HCMV-FS.

HCMV-BL than in HCMV-TB40/E (*p*-value<sub>(HCMV-BL: HCMV-TB40/E)</sub> =0.04) and HCMV-FS (*p*-value<sub>(HCMV-BL: HCMV-FS)</sub> =0.04) and was downregulated in HCMV-KM (*p*-value<sub>(HCMV-BL: HCMV-KM)</sub> =0.04) (Figure 4A). The expression of genes involved in DNA reparation (*ATM* and *MLH*) was downregulated in HMECs infected with HCMV-TB40/E, FS and KM compared to HMEC infected with HCMV-BL (*p*-value<sub>(ATM-HCMV-BL: HCMV-KM)</sub> =0.04 and *p*-value<sub>(ATM-HCMV-BL: HCMV-FS)</sub> =0.04) (Figure 4B). The gene expression of the molecules involved in cell adhesion such as E-cadherin (*CDH1*) and beta-catenin (*CTNNB1*) was minimal in HMECs infected with the four strains (BL, TB40/E, FS and KM) noting that it was mostly downregulated in HCMV-KM (*p*-value<sub>(CDH1-HCMV-BL: HCMV-KM)</sub> =0.04 and (*p*-value<sub>(CTNNB1-HCMV-BL:</sub>

HCMV-KM) =0.04) (Figure 4C). The genes involved in angiogenesis regulation *S100A4* and *EGF* were highly expressed in HMECs infected with HCMV-BL compared to HMECs infected with HCMV-FS and HCMV-KM (*p*-value<sub>(S100A4-HCMV-BL: HCMV-KM)</sub> =0.1; *p*-value<sub>(S100A4-HCMV-BL: HCMV-FS)</sub> =0.5; *p*-value<sub>(S100A4-HCMV-BL: HCMV-TB40/E)</sub> =0.1; *p*-value<sub>(EGF-HCMV-BL: HCMV-KM)</sub> =0.2; *p*-value<sub>(EGF-HCMV-BL: HCMV-FS)</sub> =0.05 *p*-value<sub>(EGF-HCMV-BL: HCMV-TB40/E)</sub> =0.5) (Figure 4D). Furthermore, the expression of genes involved in proteolysis including matrix metalloproteinase 9 (*MMP9*) and cathepsin D (*CTSD*) was 7-fold and 2.4-fold higher respectively, in HMECs infected with HCMV-BL compared to HMECs infected with HCMV-FS (Supplementary Table 4). The expression of the EMT markers for instance the

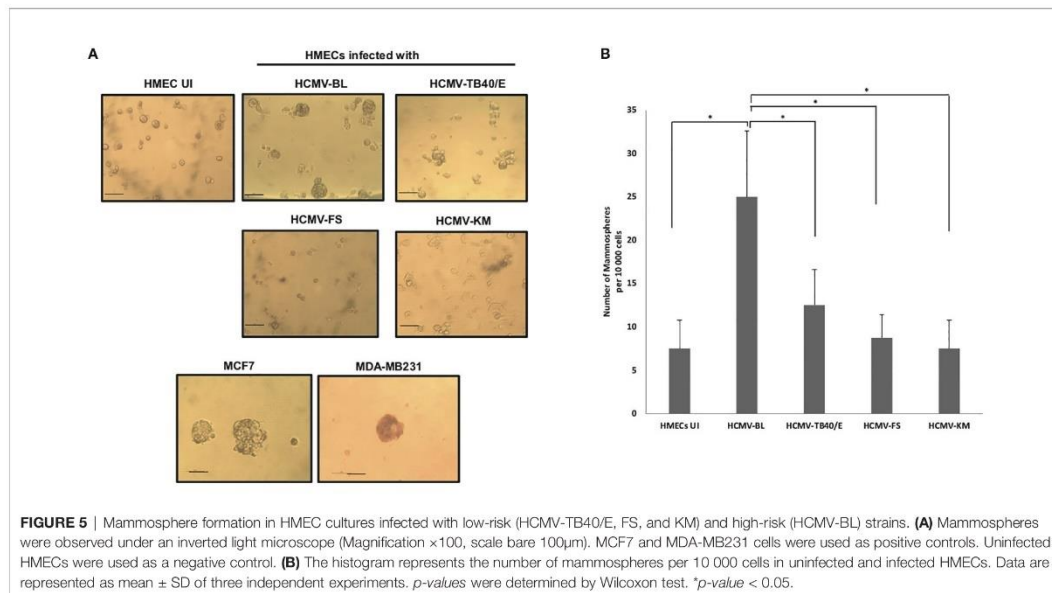

transforming growth factor-beta 1 (TGFB1) and the proto-oncogene tyrosine-protein kinase (SRC) was enhanced in HMECs infected with HCMV-BL compared to cells infected with HCMV-TB40/E (*p*-value (TGFB1- HCMV-BL: HCMV-TB40/E) = 0.04; *p*-value (SRC- HCMV-BL: HCMV-TB40/E) = 0.27), FS (*p*-value (TGFB1- HCMV-BL: HCMV-FS) = 0.12; *p*-value (SRC- HCMV-BL: HCMV-FS) = 0.12) and KM (*p*-value (TGFB1- HCMV-BL: HCMV-KM) = 0.04; *p*-value (SRC- HCMV-BL: HCMV-KM) = 0.04) (Figure 4E). In HMECs infected with HCMV-SC, the genes involved in cell survival (AKT, REL), DNA repair (MLH), and angiogenesis (S100A4) as well as the EMT marker (SRC) were regulated in a similar manner compared to HMECs infected with the FS strain (Supplementary Figure 2C).

### Mammosphere Formation in HMECs Infected With Low-risk and High-Risk HCMV Clinical Strains

We previously observed that the high-risk strains (HCMV-BL and DB) favor the appearance of stemness in chronically infected HMECs and CMV-transformed HMECs (CTH cells) (21),

further suggesting that HCMV strains that trigger cellular transformation could also promote stemness. Therefore, HMECs were infected with the high-risk strain HCMV-BL, the low-risk strains HCMV-FS and HCMV-KM, and the prototypic HCMV-TB40/E. At day 1 post-infection, mammosphere formation assay was performed as previously described (35, 36). When we challenged these HCMV-infected cultures to form mammospheres, we detected numerous mammospheres in HCMV-BL infected HMECs as previously reported for HCMV-DB infected cells (*p*-value (HCMV-BL: HMEC UI) = 0.03) (37), whereas HCMV-TB40/E displayed a limited number of mammospheres (*p*-value (HCMV-TB40/E: HMEC UI) = 0.07); only few mammospheres were observed in HMECs infected with HCMV-FS and HCMV-KM (Figure 5). The breast cancer cell lines MCF7 and MDA-MB231 generated mammospheres as previously reported (37) (Figure 5). Moreover, few mammospheres were observed in uninfected HMECs as previously described (38) (Figure 5). Altogether, we noticed a preferential formation of mammospheres in HMECs infected with the high-risk HCMV-BL strain in opposition to the low-risk HCMV-TB40E (*p*-value (HCMV-BL: HCMV-TB40/E) = 0.03), HCMV-

**FIGURE 5** | Mammosphere formation in HMEC cultures infected with low-risk (HCMV-TB40/E, FS, and KM) and high-risk (HCMV-BL) strains. **(A)** Mammospheres were observed under an inverted light microscope (Magnification  $\times 100$ , scale bar 100 $\mu$ m). MCF7 and MDA-MB231 cells were used as positive controls. Uninfected HMECs were used as a negative control. **(B)** The histogram represents the number of mammospheres per 10 000 cells in uninfected and infected HMECs. Data are represented as mean  $\pm$  SD of three independent experiments. *p*-values were determined by Wilcoxon test. \**p*-value < 0.05.

FS (*p*-value (HCMV-BL: HCMV-FS) = 0.03) and HCMV-KM (*p*-value (HCMV-BL: HCMV-KM) = 0.03) strains.

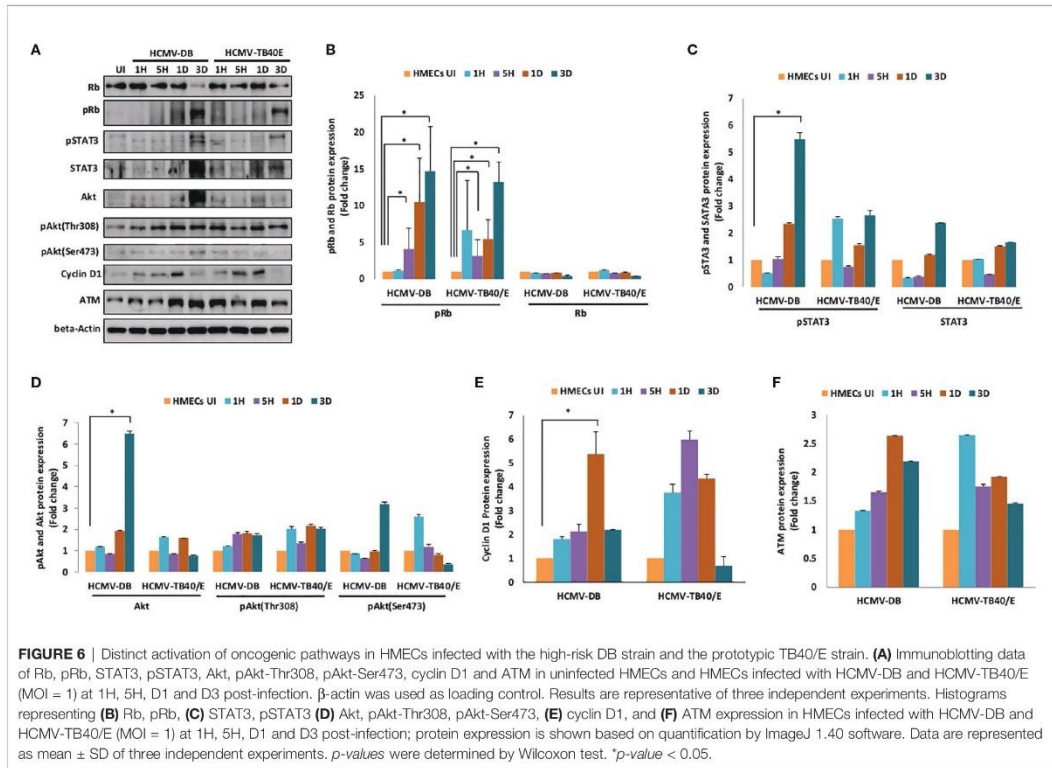

### Side-By-Side Comparison of the Prototypic Strain TB40/E and the High-Risk DB Strain for Some Specific Phenotypic and Functional Traits

Since we observed limited mammospheres in HMECs infected with HCMV-TB40/E (Figure 5) and a slight increase in telomerase activity which has been previously reported (20), we decided to compare side by side the activation of oncogenic molecular pathways in HMECs infected with HCMV-TB40/E and the high-risk HCMV-DB strain. The productive HCMV-DB and TB40/E infection was confirmed in HMECs where both confocal microscopy imaging and flow cytometry data showed the IE1 staining (Figures 1A, B). At the protein expression level (day 3 post-infection), Rb was diminished whereas pRb was highly expressed in HMEC-HCMV-DB (*p*-value (HCMV-DB: HMEC-UI) = 0.04) and to a lesser extent in HMEC-HCMV-TB40/E (*p*-value (HCMV-TB40/E: HMEC-UI) = 0.04, *p*-value (HCMV-TB40/E: HCMV-DB) = 0.8) (Figures 6A, B). At the same time point, pSTAT3 expression was higher in HMEC-HCMV-DB (*p*-value (HCMV-DB: HMEC-UI) = 0.03) compared to HMEC-HCMV-TB40/E (*p*-value (HCMV-TB40/E: HMEC-UI) = 0.06) and STAT3 expression was further increased in HMEC-HCMV-DB compared to HMEC-HCMV-TB40/E (Figures 6A, C). Further, Akt expression was highly increased in HMEC-HCMV-DB (*p*-value (HCMV-DB: HMEC-UI) = 0.03), compared to HMEC-HCMV-TB40/E at day 3 post-infection (*p*-value (HCMV-TB40/E: HMEC-UI) = 0.06), and an increase in its phosphorylation on both

serine 473 and threonine 308 in HMEC-HCMV-DB was observed (Figures 6A, D). At day 1 post-infection, cyclin D1 expression was increased in HMEC-HCMV-DB (*p*-value (HCMV-DB: HMEC-UI) = 0.03) compared to HMEC-HCMV-TB40/E (*p*-value (HCMV-TB40/E: HMEC-UI) = 0.06) (Figures 6A, E). The protein expression of ATM was elevated in HMECs infected with HCMV-DB in comparison to HCMV-TB40/E (Figures 6A, F). Our results indicate that the HCMV-TB40/E strain does not induce significant activation of the molecular oncogenic pathways, especially when compared to the high-risk strain HCMV-DB, and therefore should be classified as a low-risk HCMV strain consistent with the absence of colony formation in soft agar in HMEC cultures seeded with TB40/E.

### Detection of HCMV in Breast Cancer Biopsies

To assess the impact of HCMV strains on cellular gene expression *in vivo*, Ki67 expression was quantified by RT-qPCR in breast tumor biopsies, including luminal and basal-like tumors compared to healthy breast tissues. First, we measured the percentage of healthy and tumor biopsies with low (<30), intermediate (30–100) or high (>100) Ki67 mRNA expression (Figures 7A, B). Basal-like biopsies accounted for the highest percentage of biopsies with high Ki67 mRNA expression level (% of basal-like: 44%) compared to healthy (2%) and luminal biopsies (20%) (*p*-value (High Ki67 - Basal : Healthy) = 0.02) (Figure 7A). To further study the role of HCMV associated with Ki67 transcript expression, we assessed the presence of HCMV in the biopsies by quantifying *IE1* and *UL69* genes using qPCR (21, 30). In HCMV-positive biopsies, basal-like biopsies showed the

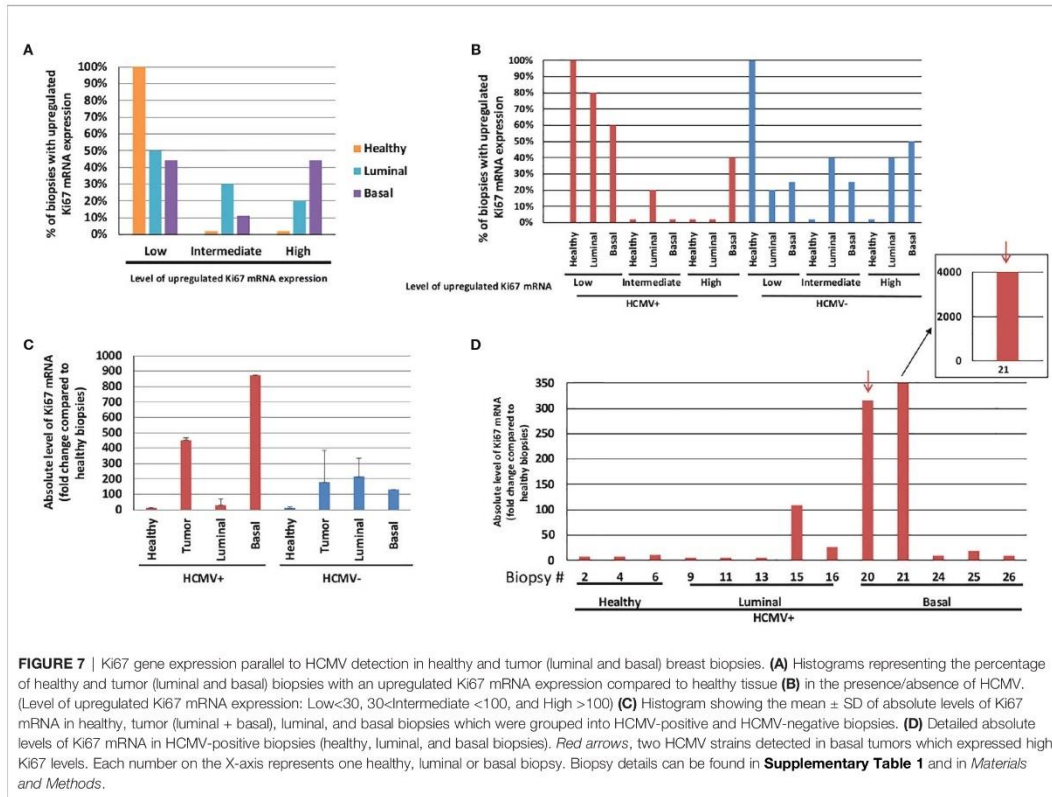

highest percentage of biopsies with high levels of Ki67 mRNA (40%) in contrast to the healthy (0%) and luminal (0%) biopsies (**Figure 7B**). Second, we assessed the absolute level of Ki67 mRNA per biopsy of healthy tissues, luminal and basal-like tumors taking into account the presence or absence of HCMV (**Figure 7C**). Healthy biopsies showed low absolute levels of Ki67 mRNA compared to tumor biopsies independent of HCMV status (presence or absence) (*p-value* = 0.02). In tumor biopsies, the absolute level of Ki67 mRNA was enhanced by 2.5-fold in HCMV-positive biopsies compared to HCMV-negative biopsies (*p-value* = 0.2). In HCMV-positive biopsies, the absolute level of Ki67 mRNA in basal tumors was enhanced by 31.45-fold compared to luminal tumors (*p-value* = 0.17) (**Figure 7C**). The absolute level of Ki67 mRNA was shown separately for each biopsy where cutoff lines were set to differentiate between low and high Ki67 expression and allow a closer look on the variability of Ki67 mRNA expression per sample (**Supplementary Figure 3**). Thus, when we independently measured the absolute level of Ki67 mRNA in each HCMV-positive biopsy, we detected two basal biopsies (biopsies #20 and #21) showing the highest absolute levels of Ki67 mRNA with 315 and 4015-fold increase versus the mean value of healthy tissue, respectively (**Figure 7D**). Meanwhile,

much lower absolute levels of Ki67 mRNA were detected in the other HCMV-positive tumor and healthy biopsies. Low absolute levels of Ki67 mRNA were detected in HCMV-positive luminal biopsies (less than 30-fold increase versus mean value of healthy tissue) except for one biopsy (biopsy #15 with 108-fold increase) (**Figure 7D**).

Within our data, we were able to identify two biopsies, namely biopsies #20 and #21 (**Figure 7D**, arrows), that could harbor high-risk HCMV strains. Given the total number of biopsies, we might not be able to properly identify all the high-risk strains, which effect might be partially masked in the overall HCMV-positive biopsies. To confirm the high-risk status of biopsies #20 and #21, we isolated the strains for each biopsy and used it to infect HMECs (**Supplementary Figure 4A**). After few weeks in culture, we observed dense structures (**Supplementary Figure 4B**), similar to the morphology of the previously reported CTH cells (20, 21). These emerging structures were not present in HMECs infected with low-risk strains that were isolated from other biopsies in which we observed cell lysis. Overall, we identified two high-risk strains (n=2; 15%) out of the HCMV-positive biopsies (n=13); upon assessing the proportion of high-risk strain within tumor biopsies only, we identified two high-risk strains (n=2; 20%) out of the total HCMV-positive tumors (n=10).

Finally, using twenty different breast tumor biopsies, we aimed at evaluating the value of Ki67 expression as an index for increased proliferation in breast cancer. Ki67 mRNA and protein levels were measured by RT-qPCR and IHC, respectively, on the same biopsy sample. A correlation was observed between Ki67 protein and mRNA levels (**Supplementary Figure 5**). This data indicates that Ki67 mRNA expression could be considered as a reliable marker for the measurement of increased proliferation in breast cancer.

**DISCUSSION**

We previously isolated the two clinical isolates, HCMV-DB and HCMV-BL, which in primary human mammary epithelial cells (HMECs) promoted oncogenic molecular pathways, established anchorage-independent growth *in vitro*, and produced tumorigenicity in mice models (20, 21), therefore named high-risk oncogenic strains. In contrast, other clinical HCMV strains such as HCMV-FS, KM and SC did not trigger such traits (21), therefore named low-risk oncogenic strains. TB40/E strain did not induce significant activation of the molecular oncogenic

pathways in HMECs, especially when compared to the high-risk strain HCMV-DB, and therefore should be classified as a low-risk HCMV strain consistent with the absence of colony formation in soft agar. In contrast to the other HCMV low-risk strains, HCMV-KM was isolated from a two-year old infant with HCMV congenital infection which might explain the different observed transcriptome profile compared to other low-risk HCMV strains (39). Our results indicate the capacity of the six tested HCMV clinical strains to replicate efficiently in HMEC cells allowing the comparison of their transcriptome profile. The transcriptome of HMECs infected with HCMV-BL strain exhibits a pro-oncogenic cellular environment with enhanced expression of several oncogenes, proliferation markers, cell survival genes, and EMT traits (**Figure 8**). Moreover, these pro-oncogenic characteristics were accompanied with stemness traits as assessed *in vitro* by mammosphere formation. In contrast, based on the transcriptome analysis, the HCMV-FS, KM and SC strains were less prone to favor an oncogenic environment (**Figure 8**). The prototypic TB40/E strain displays mostly low-oncogenic traits as assessed by its proteomic profile in infected HMECs (**Figure 8**). Finally, we observed a potential link between the presence of HCMV in the breast tumor,

**FIGURE 8** | A hypothetical model to summarize the transcriptome differences between low-risk and high-risk HCMV strains based on the modulation of cellular pathways involved in oncogenesis. In contrast to the low-risk HCMV strains (e.g. HCMV-FS, HCMV-KM and HCMV-TB40/E), the high-risk HCMV strains (e.g. HCMV-DB and HCMV-BL) strongly upregulate the expression of oncogenes, cell proliferation genes, genes involved in cell survival and EMT genes, thereby they might favor the initiation and/or the progression of basal breast tumors with poor prognosis.

especially the basal tumors, and high levels of Ki67 mRNA further suggesting the presence of high-risk HCMV strains in some of the basal tumors. Altogether, the transcriptome profiles of HCMV-infected HMECs and the analysis of Ki67 mRNA levels in breast tumors might allow for the classification of high and low-risk HCMV strains based on their oncogenic potential.

Although HCMV clinical isolates display a broad cellular tropism, the growth of laboratory HCMV strains is restricted to fibroblasts (16). Furthermore, several clinical HCMV strains can generate distinct inflammatory (M1) and immunosuppressive (M2) macrophage polarization after infection of blood monocytes and tissue macrophage and can establish latency in these latter (17, 23, 25, 40). The preferential tropism of clinical HCMV strains might favor their long-lasting low-level viral replication in HMECs and ultimately promote breast cancer (41–43). Taking into account its tropism for mammary epithelial cells and its transcriptome oncogenic environment, the HCMV-BL strain is close to the previously described HCMV-DB strain (37). Based on their transforming capacity *in vitro* (soft agar), the activation of oncogenic and proliferation pathways including Myc and Ki67 overexpression, and the development of tumors when injected in NSG mice (20, 21) the HCMV-DB and HCMV-BL strains are classified as high-risk strains.

Inactivation of tumor suppressor proteins such as retinoblastoma protein (Rb) and p53 and activation of pro-

oncogenes such as Myc and Ras are critical events involved in HMEC cells transformation and immortalization (44, 45) and are known to favor breast cancer progression (46). Intriguingly, the expression of p53 was 7-fold higher in HMECs infected with high-risk strain HCMV-BL compared to uninfected HMECs. Enhanced expression of p53 has been described in human mammary epithelial cells infected with HCMV-DB (20, 37) and in fibroblasts infected with numerous HCMV strains (47, 48). To explain the functional inactivation of p53 needed for cell transformation, a potential inhibitory effect of IE2 on p53 transcriptional activity has been previously reported (49). In addition, we previously described p53 protein binding to IE2 in HCMV-DB infected HMECs, leading to its functional inactivation parallel to p53 transcript upregulation (20, 37). A similar mechanism might be in action in HMECs infected with HCMV-BL.

Likewise, the expression of Rb gene is increased in HMECs infected with HCMV-BL by 10-fold compared to the uninfected HMECs. Several small DNA tumor viruses such as adenovirus, human papillomavirus, and polyomavirus were described to abolish the function of Rb protein (50). In addition, it was reported that Rb inactivation mediated by viral proteins through the E2F transcriptional factor is necessary for viral replication and mammalian cells transformation (50, 51). Also, the inactivation of Rb protein could be caused by post-translation phosphorylation (52). For HCMV, manipulation of

the cell cycle through Rb inactivation could favor cell transformation (53). First, the viral protein pp71 degrades the hypophosphorylated Rb protein earlier during infection, then Rb protein reaccumulates later during infection (54–56). Second, the viral protein UL97 phosphorylates Rb protein on several CDK target sites and deactivates it. Third, the viral proteins IE1 and IE2 were described to activate E2F-responsive promoters and most probably induce Rb inactivation (57–59). Interestingly, parallel to enhanced Rb gene expression we observed high levels of E2F1 transcript in HMECs infected with the high-risk BL strain. Thus, the inactivation of both p53 and Rb proteins is mandatory for cell transformation in HCMV-BL and HCMV-DB infected HMECs which might explain that even under enhanced p53 and Rb gene expression, their protein activity will be abolished.

In agreement with our previous results (21), the overexpression of Myc and KRas could participate in the transformation process of HMEC cells infected with HCMV-BL. In addition, the enhanced expression of other oncogenes such as Jun and E2F1 observed in HMECs infected with HCMV-BL could stimulate transformation (60, 61). Interestingly, the viral proteins IE1 and IE2 induce Myc activation (62). We observed previously a similar activation of Myc and Ras protein and gene expression in HMECs infected with the HCMV-DB strain (20, 37).

Furthermore, one of the mechanisms described to transform HMECs is the link of Myc overexpression to PI3K/Akt pathway activation (63, 64). We observed mostly enhanced expression of Akt gene in HMECs infected with HCMV-BL compared to HCMV-FS, KM and TB40/E in agreement with our previous results (21), and an upregulation of serine-473 phosphorylation of Akt in HMECs infected with HCMV-DB compared to HCMV-TB40/E. The PI3K/Akt activation in HCMV infected cells is in line with previous findings (65). In addition, several studies have pointed the role of REL in cell growth and oncogenesis (66). The overexpression of REL was associated with cell transformation *in vitro* and/or *in vivo*. Epstein-Barr virus (EBV) activates REL/NF- $\kappa$ B during malignant transformation (67). Thus, the overexpression of REL in HMECs infected with HCMV-BL is consistent with its high oncogenic potential.

In agreement with the HCMV-DB transcriptome study (37), an enhanced expression of proliferation markers such as STAT3, cyclin D1, and especially Ki67 was observed in HMEC cells infected with HCMV-BL but not with HCMV-FS, KM, SC and TB40/E. The proliferation and invasion of several cancers could be explained by STAT3 activation and cyclin D1 overexpression (68). Moreover, the overexpression of pSTAT3 and STAT3 at day 3 post-infection was observed mainly in HMECs infected with HCMV-DB, but to a lesser extent with HCMV-TB40/E. These findings confirm that the high-risk HCMV strains such as BL and DB have high proliferation capacities compared to the low-risk HCMV strains, such as TB40/E, FS, KM and SC.

Studies have reported that ataxia telangiectasia mutated (ATM) is required for efficient viral replication of numerous viruses including HCMV, HSV-1, HPV, and HIV (69–73). Indeed, HCMV infection leads to host DNA damage responses (DDRs) with activation of the DNA repair pathway (74–76).

Enhanced expression of ATM gene was observed in infected HMECs with HCMV-BL and with HCMV-DB as reported previously (37). Lower levels of ATM expression were detected in HMECs infected with HCMV-TB40/E, FS, and KM. The enhanced expression of ATM can promote genome instability resulting in cellular transformation. MLH expression is necessary for efficient HSV-1 viral replication (77) and its enhanced expression has been linked to high levels of genomic instability, cancer progression, and aggressiveness (78, 79). Likewise, the overexpression of MMP9 and CTSD observed in HMECs infected with HCMV-BL was associated with the most aggressive subtype of breast cancer (80), tumor cell invasion, and metastasis (81–84).

The expression of genes involved in EMT such as the proto-oncogene tyrosine-protein kinase Src (85) and the transforming growth factor-beta 1 (TGFB1) (86, 87) was higher in HMECs infected with HCMV-BL than with HCMV-TB40/E, FS, KM and SC. Our findings are in accordance with our previous analysis of HCMV-DB transcriptome (37).

Altogether the transcriptome analysis of HMECs infected with the high-risk strain HCMV-BL underlines the potential capacity of the emergence of cancer stem cells (CSCs) compared to the HMECs infected with low-risk strains (HCMV-FS, KM and SC). In line with our transcriptome data and with the previously reported enhanced mammosphere formation in HMECs infected with HCMV-DB (37), we observed that the number of mammospheres detected in HMECs infected with HCMV-BL was 2-fold, 2.8-fold and 3-fold higher compared to HMECs infected with HCMV-TB40/E, HCMV-FS and KM, respectively.

The distinct oncogenic potential of HCMV strains observed at the transcriptome level *in vitro* was then assessed *in vivo* in breast tumors. The nuclear protein Ki67 is not required only for cell proliferation in tumor but also for tumor initiation, growth, and metastasis. Moreover, Ki67 inactivation leads to transcriptome remodeling that alters mesenchymal-epithelial balance and suppresses stemness (88). Ki67 is highly expressed in malignant tissues with poorly differentiated tumor cells (89). High Ki67, possessing high proliferation potential, was reported to worsen the survival of triple negative breast cancer patients and to trigger quick tumor recurrence within a short period of time (90). Remarkably, enhanced expression of Ki67 gene and upregulation of Ki67 protein was observed in HMECs infected with the HCMV-DB and BL strains (20, 21). Therefore, we assessed the link between HCMV presence and Ki67 gene overexpression in breast tumor biopsies. Basal-like biopsies revealed the highest percentage of biopsies with high levels of Ki67 mRNA compared to the healthy and luminal biopsies. Only tumor biopsies were impacted by HCMV status; the highest level of Ki67 mRNA was detected in HCMV-positive tumor biopsies compared to HCMV-negative tumor biopsies. Among the HCMV-positive biopsies, the absolute level of Ki67 was low in all healthy and most of the luminal biopsies except for one luminal biopsy (#15 with limited increase in Ki67 absolute level). In contrast, among the tested basal-like HCMV-positive biopsies, we observed augmented absolute levels of Ki67 mRNA in two biopsies (biopsies #20 and #21) despite the low absolute levels of Ki67 mRNA that were detected in some biopsies.

The HCMV strains that were isolated from biopsies #20 and 21, transformed the freshly uninfected HMECs resulting in the appearance of CMV-transformed HMECs (CTH cells) *in vitro* indicating their high-risk profile (**Supplementary Figure 4**). Since high-risk HCMV strains strongly enhanced the expression of Ki67Ag (20, 21), the majority of the HCMV strains detected in the breast tumor biopsies or in the adjacent tested healthy tissues might be non-oncogenic or low-risk HCMV strains. The detection of very high expression of Ki67 mRNA in two basal tumor biopsies concomitant with the presence of HCMV suggests a potential link between high-risk HCMV strains present in the tumor tissue, highly enhanced Ki67 expression, and the initiation and/or progression of basal breast tumors. In agreement with our results, Ki67 was described as a key marker associated with poor prognosis in triple-negative breast cancer (91). We are currently studying a larger cohort of breast cancer biopsies and assessing additional “oncogenic” markers such as c-Myc to further highlight the exact role of HCMV strains in breast oncogenesis.

## CONCLUSION

In conclusion, our data indicate the capacity of high-risk HCMV strains to induce a pro-oncogenic cellular environment in contrast to the low-risk strains. Similar to the HCMV-DB strain, HCMV-BL was able to induce enhanced expression of various oncogenes, genes involved in proliferation, cell survival, DNA repair, and EMT. Additionally, high-risk HCMV strains present stemness traits with enhanced mammosphere formation *in vitro* compared to the low-risk strains. *In vivo*, we detected the concomitant presence of a very high Ki67 gene expression in two HCMV-positive basal breast tumors, indicating a potential link between high-risk HCMV strains present in the tumoral tissue and the development of aggressive tumors of poor prognosis. The discrimination between HCMV clinical strains based on their distinct oncogenic potential will pave the way for understanding their respective role in breast cancer and open the door to new therapeutic approaches.

Nehme Z, Pasquereau S, Haidar Ahmad S, **El Baba R**, Herbein G. Polyploid giant cancer cells, EZH2 and Myc upregulation in mammary epithelial cells infected with high-risk human cytomegalovirus. *EBioMedicine* 2022;80:104056. <https://doi.org/10.1016/j.ebiom.2022.104056>.

Human cytomegalovirus (HCMV) infection has been associated with complex cancer processes. Herein, we explored the molecular mechanisms underlying HCMV-induced oncogenesis. We have identified EZH2 as a downstream target for HCMV-induced Myc upregulation during acute and chronic infection with high-risk strains. This leads to the development of giant cells and acquisition of embryonic stemness markers in CMV-transformed cells. We also found that EZH2 inhibitors can mitigate the malignant properties of these cells. Breast biopsies with HCMV were characterized by elevated EZH2 and Myc expression, and this correlated with the presence of giant cancer cells. Further, we isolated two oncogenic HCMV strains from basal-like tumors with high EZH2 and Myc levels. This study suggests a connection between HCMV-induced Myc activation, EZH2 upregulation, and the development of polyploidy, supporting the idea that EZH2 and Myc play a role in tumorigenesis. Additionally, EZH2 is identified as a potential therapeutic target for breast cancer, especially in the presence of HCMV infection.

# Polyloid giant cancer cells, EZH2 and Myc upregulation in mammary epithelial cells infected with high-risk human cytomegalovirus

## Summary

**Background** Human cytomegalovirus (HCMV) infection has been actively implicated in complex neoplastic processes. Beyond oncomodulation, the molecular mechanisms that might underlie HCMV-induced oncogenesis are being extensively studied. Polycomb repressive complex 2 (PRC2) proteins, in particular enhancer of zeste homolog 2 (EZH2) are associated with cancer progression. Nevertheless, little is known about EZH2 activation in the context of HCMV infection and breast oncogenesis.

**Methods** Herein, we identified EZH2 as a downstream target for HCMV-induced Myc upregulation upon acute and chronic infection with high-risk strains using a human mammary epithelial model.

**Findings** We detected polyploidy and CMV-transformed HMECs (CTH) cells harboring HCMV and dynamically undergoing the giant cells cycle. Acquisition of embryonic stemness markers positively correlated with EZH2 and Myc expression. EZH2 inhibitors curtail sustained CTH cells' malignant phenotype. Besides harboring polyloid giant cancer cells (PGCCs), tumorigenic breast biopsies were characterized by an enhanced EZH2 and Myc expression, with a strong positive correlation between EZH2 and Myc expression, and between PGCC count and EZH2/Myc expression in the presence of HCMV. Further, we isolated two HCMV strains from EZH2<sup>High</sup>Myc<sup>High</sup> basal-like tumors which replicate in MRC5 cells and transform HMECs toward CTH cells after acute infection.

**Interpretation** Our data establish a potential link between HCMV-induced Myc activation, the subsequent EZH2 upregulation, and polyploidy induction. These data support the proposed tumorigenesis properties of EZH2/Myc, and allow the isolation of two oncogenic HCMV strains from EZH2<sup>High</sup>Myc<sup>High</sup> basal breast tumors while identifying EZH2 as a potential therapeutic target in the management of breast cancer, particularly upon HCMV infection.

**Funding** This work was supported by grants from the University of Franche-Comté (UFC) (CR3300), the Région Franche-Comté (2021-Y-08292 and 2021-Y-08290) and the Ligue contre le Cancer (CR3304) to Georges Herbein. ## Introduction

Human cytomegalovirus (HCMV), or human herpesvirus 5 (HHV-5), is a ubiquitous DNA virus with a mid to high seroprevalence, reaching up to 95% of the adult population worldwide.<sup>1</sup> Beyond the paradigm of oncomodulation, HCMV infection and viral products fulfill the criteria of cancer hallmarks updated by Hanahan and Weinberg to rationalize the complexities of neoplastic disease,<sup>2,3</sup> with viral proteins and/or nucleic acids

**Research in context***Evidence before this study*

Beside the fact that the majority of the adult population worldwide are human cytomegalovirus (HCMV)-seropositive, HCMV infection and viral products meet the criteria of cancer hallmarks in which HCMV-viral products are being detected in multiple cancers. Most importantly, recent evidence reveals that HCMV gene products are found in more than 90% of tumors and metastases of breast cancers, and their augmented expression can be linked to a more aggressive phenotype. To intervene in the development and implementation of effective diagnostic, preventive, and therapeutic measures, we must imperatively identify HCMV's mechanism of action in breast cancer. Recent data demonstrated that polyploidy giant cancer cells play a critical role in breast cancer pathophysiology. Polyploid giant cancer cells (PGCCs) or tumorigenesis drivers were mostly detected in poorly differentiated and therapy resistant cancers. Previously, we showed that the infection with the two clinical strains HCMV-DB (KT959235) and HCMV-BL (MW980585) induces HMECs transformation into CMV-Transformed HMECs (CTH cells). CTH cells presented a polyploid phenotype, stemness, epithelial-to-mesenchymal plasticity which resulted in fast growing breast tumors in NSG mice.

*Added value of this study*

Given the oncogenic properties of enhancer of zeste homolog 2 (EZH2) and Myc especially in high-grade breast cancer, in the present study, we intended to assess the link between HCMV, PGCCs, EZH2, and Myc in the context of breast cancer development and progression. Originally, our findings show that high-risk HCMV strains can promote a polyploid phenotype and reveal the existence of a potential link between HCMV infection, Myc/EZH2 upregulation and polyploidy generation *in vitro* and in basal breast tumors. Altogether, our findings confirm the proposed tumorigenic properties of EZH2 and Myc in the context of HCMV infection.

*Implications of all the available evidence*

A better understanding of the potential link between HCMV and breast cancer will pave the way for new targeted therapies thus increasing the overall survival of breast cancer patients.

being detected in a multitude of cancer types.<sup>4</sup> For instance, in the context of breast cancer, HCMV proteins were confined to neoplastic cells in primary tumors, sentinel lymph node<sup>5,6</sup> and brain metastases, with shorter overall survival and time to tumor progression in patients having the highest expression of HCMV immediate early (IE) proteins.<sup>7</sup> Recently, productive HCMV infection in breast tumor cells has been reported and could indicate that HCMV replication may play a role in breast cancer progression.<sup>8</sup> This

rationalizes the urgent need to actively dissect the exact etiological role of HCMV in the relevance of breast cancer in order to contribute to the development of novel diagnostic, preventive, or therapeutic strategies.

On the other hand, polyploid giant cancer cells (PGCCs) are recognized as a cancerous cellular subpopulation endowed with an enhanced tumorigenic properties, tumor maintenance and recurrence, as well as therapy resistance, the latter accentuated by tumor heterogeneity.<sup>9–11</sup> Giant cancerous cells were described in a wide range of high-grade cancers, chemoresistant tumors and cancer cell lines, for instance glioma, breast, lung, prostate and colorectal cancer.<sup>12</sup> Being greatly dedifferentiated with embryonic stem-like traits, PGCCs are able to replicate through an asymmetric division pattern, resulting in the establishment of a mitotically-competent progeny population.<sup>13</sup> Remarkably, a shared characteristic among all malignancies triggered by oncoviruses is the presence of polyploidy, highlighting PGCCs as keystone phenotype in virally-induced tumors.<sup>14</sup>

Being the enzymatic subunit of polycomb repressive complex 2 (PRC2), enhancer of zeste homolog 2 (EZH2) is a histone-lysine N-methyltransferase responsible of transcriptional silencing.<sup>15</sup> EZH2 aberrations are associated with the development and progression of a variety of cancers.<sup>16,17</sup> Indeed, high EZH2 levels, notably in triple-negative breast cancer,<sup>18</sup> are strongly associated with poor clinical outcome<sup>19</sup> and correlate with aggressive pathologic features, including high nuclear grade and proliferative index.<sup>18</sup> In parallel, EZH2 was shown to expand the stem cell pool and the breast tumor initiating cells, including luminal progenitor cells, hence enhancing accelerated breast cancer initiation, metastasis and growth.<sup>20–22</sup> Interestingly, *EZH2* is identified as a downstream target of Myc oncogene, the latter coordinately regulating *EZH2* through transcriptional and post-transcriptional mechanisms during tumor initiation and disease progression.<sup>23,24</sup> On the other hand, EZH2 was shown to be recruited to the major immediate early promoter (MIEP) in CD14+ monocytes where HCMV establishes latent infection *in vivo*.<sup>25</sup> Further, EZH2 was demonstrated to be overexpressed in glioblastoma multiforme tissues harboring HCMV.<sup>26</sup> Intriguingly, EZH2 is overexpressed in PGCCs,<sup>27,28</sup> the latter being also triggered by HCMV infection,<sup>29</sup> which points toward a potential link between HCMV, PGCCs, and EZH2.

Previously, we demonstrated that the infection with the clinical strains HCMV-DB (KT959235) and HCMV-BL (MW980585) induces HMECs transformation into CMV-Transformed HMECs (CTH), the latter displaying a polyploid phenotype, stemness, epithelial-to-mesenchymal (EMT) plasticity, and resulting in the appearance of fast growing breast tumors in NSG mice.<sup>29,30</sup> Given the stated EZH2 oncogenic functions, we aimed to evaluate the presence of a potential link between the

triad of HCMV, PGCCs and EZH2, as well as the potential interrelation with Myc in the context of breast carcinogenesis. Subsequently, in the present study, we assessed the activation of Myc, EZH2 and SUZ12 expression, as well as ploidy levels following acute infection with low- or high-risk HCMV strains.<sup>31</sup> This was complemented by deciphering the morphological and phenotypic characteristics of CTH cells undergoing the giant cell cycle and the potential implication of Myc and PRC2 proteins in both CTH cells and breast cancer biopsies.

## Materials and methods

### Cell lines and culture

Human primary mammary epithelial cells (HMECs, A10565) and embryonic lung fibroblasts (MRC5, 84002) were purchased from Life Technologies (Carlsbad, CA, USA) and RD-Biotech (Besançon, France), respectively. Human breast cancer cell lines MDA-MB231 and MCF7 were obtained from Institut Hiscia (Arlesheim, Switzerland). MRC5, MDA-MB231 and MCF7 cells were grown in Dulbecco's modified Eagle medium (DMEM) (PAN-Biotech) supplemented with fetal bovine serum (Dutscher) and penicillin/streptomycin (Life Technologies) (10% and 1% final concentration, respectively). HMECs were cultured in HMEC medium (Life Technologies) supplemented with HMEC supplement and bovine pituitary extract (Life Technologies) at 37 °C, 5% CO<sub>2</sub> and 95% humidity. CTH cells emerging following chronic infection with HCMV-BL and HCMV-DB isolates were cultured in the same condition as HMECs. Mycoplasma monthly screening was performed to certify mycoplasma free cultures (Venor-Gem classic mycoplasma detection, Minerva biolabs).

### HCMV clinical isolates growth and detection

HCMV-FS, HCMV-KM, HCMV-BL, and HCMV-DB clinical strains were isolated from patients hospitalized at Besançon University Hospital (France). The clinical and biological data for the four hospitalized patients from whom we isolated the HCMV-DB, BL, FS and KM strains were provided (Suppl. Table 1). Viral stocks were prepared and stored at -80 °C as detailed previously.<sup>29</sup> The presence of ULb' region was detected in all the four strains as well as in the B544 and B693 strains isolated from the triple negative breast cancer (TNBC) tissues (see below), as measured by the detection of UL128/UL130/UL131 by qPCR (Suppl. Fig. 1). Infection of HMECs or MRC5 ( $1 \times 10^6$ ) cells with the clinical isolates was carried out at a multiplicity of infection (MOI) of 1. Briefly, cells were incubated at 37 °C for 2 h, after which the inoculum was discarded, and the cellular monolayer was washed thoroughly three times with 1X PBS and covered with fresh medium. To determine viral kinetics,

infectious cell-free supernatant was harvested at the indicated time points post-infection, DNA was isolated (EZNA Blood DNA Kit, D3392-02, Omega BIO-TEK) and real-time IER quantitative PCR (qPCR) was performed using a Stratagene Mx3005P thermocycler (Agilent), using IER primers (Suppl. Table 2). qPCR was performed using KAPA SYBR FAST Master Mix (KAPA BIOSYSTEMS, KK4601) and reactions were activated at 95 °C for 10 min, followed by 50 cycles (15 s at 95 °C and 1 min at 60 °C). Results were collected and analyzed using MxPro qPCR software. Where indicated, HCMV lncRNA4.9 was determined by PCR assay by using DreamTaq DNA polymerase (EP0701, Thermo Scientific). PCR products were resolved by agarose gel electrophoresis and SYBR Green I (Roche) was used for visualization.

### Microscopy

CTH cells were monitored using an Olympus optical microscope (Japan) and OPTIKA microscopy digital camera (Opticam, Italy). To study the giant cell cycle, confocal microscopy was used and DAPI (4', 6'-diamidino-2-phenylindole) staining was performed according to the manufacturer's protocol. To assess the expression of EZH2, SUZ12, Myc, pp65, and HCMV late Ag, uninfected HMECs and CTH cells were washed with 1X PBS, fixed and permeabilized (BD Cytotfix/Cytoperm, 554722). Primary antibodies targeting EZH2, SUZ12, Myc, pp65, and HCMV late Ag (Suppl. Table 3) were used in parallel to DAPI staining. After staining, slides were evaluated using 63X oil immersion objective lens with a Carl-Zeiss confocal microscope (Germany). Images were analyzed using ZenBlue Software (Carl-Zeiss Microscopy GmbH).

### Western blotting

Western blotting was performed as described previously.<sup>30,32</sup> Lysates from uninfected HMECs, CTH cells, MDA-MB231 and MCF7 were used to examine the expression of EZH2 and SUZ12. Lysates from uninfected HMECs and CTH cells were used to determine Myc expression. Antibodies used are listed in supplementary Table 3. Densitometry using ImageJ 1.40 software (National Institutes of Health, Bethesda, MA, USA) was employed to quantify protein levels.  $\beta$ -actin (A5316, St. Louis, MO, USA) was used as control to normalize sample loading.

### Flow cytometry analysis

Uninfected HMECs and CTH cells collection, fixation, permeabilization, staining, and incubation were performed as described previously.<sup>29</sup> Cytofluorometric analysis was performed using a BD LSRFortessa X-20 (BD Biosciences) flow cytometer. FACSDiva software (BD Biosciences) was used to collect and analyze data.

Staining was performed for EZH2, SUZ12, Oct4, SSEA4, Nanog, Tra-1-60, SOX2, Akt, pAkt(Ser473), STAT3, pSTAT3, EpCAM, CD49f, Vimentin, E-Cadherin, CD24 and CD44. Antibodies used are listed in supplementary Table 3. Proliferation of CTH cells left untreated or treated with EZH2 inhibitors was assessed by measuring Ki67 antigen (Ag) expression by intracellular flow cytometry as described previously.<sup>33</sup> For cell cycle analysis, uninfected HMECs or HCMV-infected HMECs were washed in 1X PBS, fixed in 70% ethanol and resuspended in 50 µg/ml propidium iodide (P3566, life technologies, Eugene, USA) with 0.1 mg/ml RNase (R4642, Sigma-Aldrich, Saint-Louis, MO, USA), then incubated at 37°C for 30 min as described previously.<sup>34</sup>

#### RNA cross-linking immunoprecipitation (RNA CLIP) assay

RNA Cross-linking Immunoprecipitation (RNA CLIP) was performed on CTH cells as previously reported.<sup>25</sup>

#### Semi-quantitative reverse-transcriptase polymerase chain reaction (RT-PCR)

Total RNA was extracted using E.Z.N.A.<sup>®</sup> Total RNA Kit I (Omega Bio-Tech, GA, USA) according to the manufacturer's instructions. SuperScript IV First-Strand Synthesis kit (Invitrogen, Carlsbad, CA, USA) was used for reverse transcription. Semi-quantitative PCR was performed for Oct4, SSEA-4 synthase, Nanog, Tra-1-60, SOX2 and  $\beta$ -globin expression. Primers used are listed in supplementary Table 2. Two µl target cDNA conversion mixture was amplified using DreamTaq DNA polymerase (EP0701, 83 Thermo Scientific). RT-PCR products were electrophoresed on a 2% agarose gel stained with SYBR Green I (Roche).

#### EZH2 inhibition assay

The EZH2 inhibitors EPZ6438 and GSK343 (Cayman Chemical, Ann Arbor, MI, USA) were dissolved in Dimethyl Sulfoxide (DMSO) (Sigma-Aldrich). CTH cells were left untreated or treated by EZH2 inhibitors at 0.1µM and fresh drugs were added every two days.

#### Soft agar colony formation and colorimetric MTT assays

CTH cells left untreated or treated with EZH2 inhibitors at 0.1µM and HMECs infected with HCMV-B544 and HCMV-B693 strains were seeded in soft agar (Colorimetric assay, CB135; Cell Biolabs Inc., San Diego, CA) as described previously.<sup>35</sup> After 15 days of incubation, colonies quantification was performed using MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide) assay as described previously<sup>30</sup> and soft agar colonies were observed under an Olympus microscope (magnification 200×).

#### Mammosphere assay

CTH cells untreated or treated with EZH2 inhibitors were cultured in 2 mL of mammosphere media (CCM012, R&D Systems, Minneapolis, MN, USA) supplemented with 2U/ml heparin (2812, Bio-Techne, Minneapolis, MN, USA) and 0.5 µg/ml hydrocortisone (4093, Bio-Techne, Minneapolis, MN, USA), in an ultra-low attachment surface 96-well plate. Mammospheres were observed using an Olympus optical microscope (Japan).

#### Chromatin immunoprecipitation (ChIP) assay

ChIP was performed using a Chromatin Immunoprecipitation assay kit (Millipore, cat no. 17-295) as previously described.<sup>36</sup> Chromatin cross-linking was achieved via a 10-min treatment of nuclear extracts with 1% formaldehyde at 37°C. Cross-linked lysates were sonicated to shear the DNA to an average length of 300 to 1000 base pairs. Following sonication, the lysates were pre-cleared via incubation with a 50% slurry of salmon sperm DNA/Protein A Agarose for 30 min. The pre-cleared supernatants were incubated with the primary antibodies anti-H3K27me3, anti-H3K4me3, and total anti-H3 (1:50 dilution, Suppl. Table 3) overnight and then with salmon sperm DNA/Protein A agarose beads at 4°C for 1 h. Following multiple washes, the DNA-protein complexes were eluted and the DNA was recovered by reversing the cross-linking with NaCl and proteinase K. The DNA was then extracted using the Qiaquick PCR Purification Kit (Qiagen, cat. no 28106) and analyzed by SYBR-Green real-time qPCR. The immunoprecipitated samples, along with the input DNA, were amplified for the HCMV MIEP enhancer (Enh) (Suppl. Table 3).

#### Genomic analysis of HCMV strains

The analysis of HCMV-DB and BL genomes and their comparison to other HCMV strains including the two laboratory adapted strains AD-169 and Towne in addition to Merlin, Toledo, TR, PH, VR1814, Davis, JP, and TB40/E (clinical strains with low passages in culture) was done using the NCBI nucleotide blast tool (<https://blast.ncbi.nlm.nih.gov/BlastAlign.cgi>). The phylogenetic analysis was performed as previously reported.<sup>37</sup>

#### Breast cancer biopsies

Tumor breast biopsies (luminal tumor biopsies n=10 and basal tumor biopsies n=9) and adjacent healthy breast biopsies (n=8) were provided by the Regional tumor bank (BB0033-00024 Tumorothèque Régionale de Franche-Comté). A written informed consent for participation was obtained from all patients. The study was authorized by the local ethics committees of Besançon University Hospital (Besançon, France) and the French Research Ministry (AC-2015-2496, CNIL n°1173545, NF-S-138 96900 n°F2015). Hematoxylin and eosin

slides were used to detect PGCCs presence based on Zhang et al. description, with PGCCs being defined as a cancer cell with a nucleus at least three times larger than that of a diploid cancer cell.<sup>38</sup> RNA was extracted from the biopsies using E.Z.N.A.<sup>®</sup> Total RNA Kit I (Omega Bio-Tech, GA, USA). Reverse transcription was performed using the SuperScript IV First-Strand Synthesis kit (Invitrogen, Carlsbad, CA, USA). Expression of EZH2, Myc, and GAPDH was assessed by real-time qPCR using KAPA SYBR FAST Master mix (KAPA BIOSYSTEMS, KK4601) and specific primers for EZH2, Myc and GAPDH (Suppl. Table 2) according to the manufacturer's protocol. Fold change expression was calculated using the delta-delta Ct method.<sup>39</sup>

The two strains, B544 and B693, were isolated from patients with TNBC. The treatment, clinical outcome and pathological data for these two TNBC patients were provided (Suppl. Table 4). HCMV strains, B544 and B693, were isolated by mechanical tissue disruption and filtration of the frozen biopsy through a 0.45 µm filter and initially grown on MRC5 cells. The supernatant from MRC5 culture was filtrated through a 0.45 µm filter and used to infect HMECs. The purity of our HCMV cultures was confirmed by ruling out the presence of other viruses (Epstein-Barr virus, human papillomavirus, Kaposi sarcoma herpesvirus and adenovirus).

#### Statistical analysis

All quantitative results are reported as mean ± SD of independent experiments and analyzed by using statistical software SPSS 23. Statistical analyses were performed using Mann-Whitney U test, and correlation analyses were done using Pearson and Spearman correlation tests. Differences with  $p\text{-value} \leq 0.05$  were considered significant and all exact  $p\text{-values}$  were provided in each figure. Microsoft Excel was used to construct the plots and histogram data.

#### Role of funding source

The funders had no role in the study design, data collection, data analyses or interpretation, manuscript writing, or publication decisions.

#### Reagent validation

Relevant documentation on reagent validation (antibody, cell lines, viruses) has been provided in the Supplemental Data Reagent Validation file.

## Results

### Myc and EZH2 activation parallels polyploidy induction in HMECs acutely infected with high-risk HCMV

We previously reported the replication of the clinical strain HCMV-DB in HMECs *in vitro*.<sup>30</sup> In the present

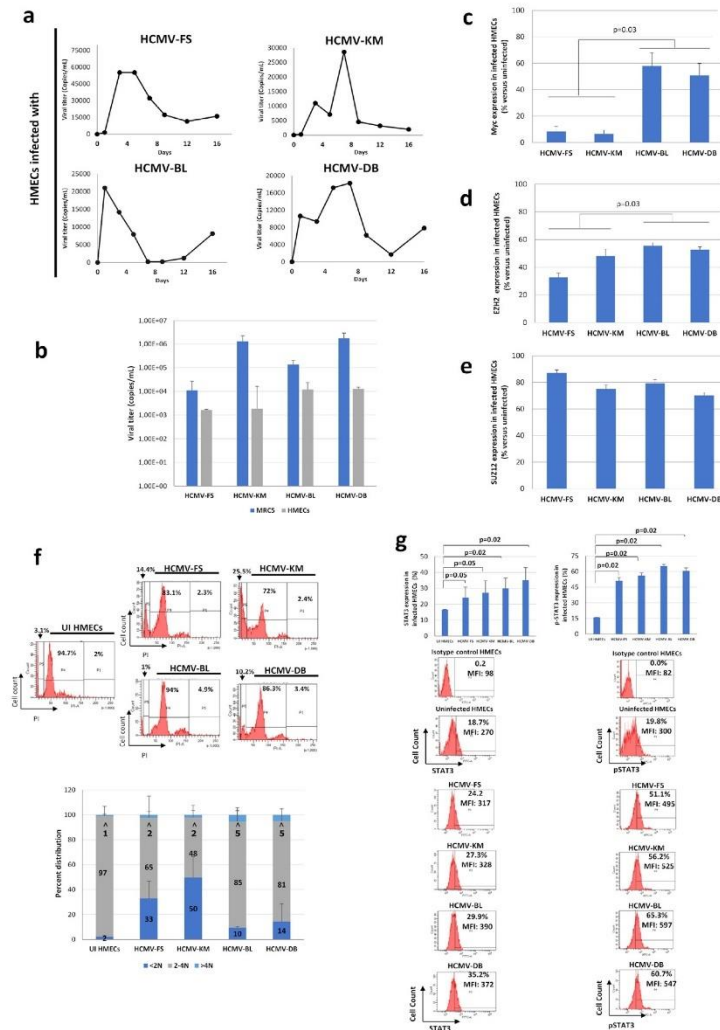

study, we infected HMECs with three newly isolated HCMV clinical isolates that we previously sorted into low- (HCMV-KM, HCMV-FS) and high- (HCMV-DB, HCMV-BL) risk oncogenic strains,<sup>29,31</sup> as well as the already described HCMV-DB strain. All strains productively replicated in HMECs with the peak viral titer detected between day 1 and 8 post-infection (Figure 1a) due to the conservation of an intact ULb' region<sup>29</sup> required for infection of epithelial/endothelial cells.<sup>40</sup> As control, productive infection peak level was lower by 1 to 3 logs in HMECs compared to MRC5 fibroblasts (Figure 1b).

Previously, activation of proto-oncogenes, including Myc was reported as an early event upon HCMV infection.<sup>41</sup> We detected higher expression levels of Myc and EZH2 in HMECs infected with high-risk strains compared to low-risk ones ( $p\text{-value} = 0.03$  and  $0.03$ , respectively; [Mann-Whitney U test]) (Figures 1c and d, Suppl. 2). No distinct pattern of SUZ12 expression variances was noted between low- and high-risk strains (Figures 1e, Suppl. 2). In parallel, we detected a higher percentage of  $<2N$  population in HMECs infected with HCMV-FS and HCMV-KM, versus a higher percentage of  $>4N$  population in HMECs infected with HCMV-BL and HCMV-DB (Figure 1f), pointing toward a higher polyploidy induction with the high-risk strains.

As we have previously demonstrated the activation of JAK/STAT3 axis in primary human hepatocytes and HepG2 cells infected with HCMV,<sup>33</sup> we observed an increase in STAT3 phosphorylation and STAT3 protein in HMECs infected with the four strains at day 1 post-infection (Figure 1g). EZH2 inhibitors and ganciclovir partially blocked the upregulation of P-STAT3 and STAT3 observed in HMECs acutely infected with HCMV, mostly in cultures infected with the high-risk DB strain (Suppl. Figure 3).

### CTH cells and giant cells cycling in HMECs chronically infected with high-risk HCMV strains

HMECs cultures were individually infected with the four isolates to monitor long-term cultures.<sup>30</sup> As control, uninfected cells were used, the latter being discontinued after 50 days due to cellular senescence, as well as for HMECs infected with the low-risk HCMV-FS and HCMV-KM strains. Notably, CTH cells emerged only with HMECs infected with HCMV-BL and HCMV-DB isolates, with cells being heterogeneous in terms of shape and size (Figure 2). Compared to uninfected cultures that displayed typical epithelial-like morphology (Figure 2a1), we observed a mixture of spheroids and giant cells dispersed among small cells, with morphological heterogeneity ranging from mesenchymal, epithelial, and fibroblastic-like structures to small spore-like cells (Figure 2). We were able to cluster the detected shapes into elongated cells, round dark cells, and big flat cells.

**Figure 1.** Replication of HCMV clinical strains in HMECs with activation of oncogenic pathways and increased polyploidy. **a**, Time-course of the viral titer in supernatant of HMECs infected with the strains HCMV-FS, HCMV-KM, HCMV-BL and HCMV-DB, as measured by IE1 qPCR. **b**, Comparison of peak viral titer in supernatant of HMECs and MRC5 cells infected with the strains HCMV-FS, HCMV-KM, HCMV-BL and HCMV-DB, as measured by IE1 qPCR. **c**, **d**, **e**, Comparison of the expression of (c) Myc, (d) EZH2 and (e) SUZ12, in HMECs infected with the strains HCMV-FS, HCMV-KM, HCMV-BL and HCMV-DB. Histograms represent mean values  $\pm$  SD of 3 independent experiments. **f**, Cell population repartition based on DNA content, as marked by PI staining of HMECs infected with the strains HCMV-FS, HCMV-KM, HCMV-BL and HCMV-DB. Cells are classified between <2N, 2-4N and >4N populations. Histograms represent the mean  $\pm$  SD of 3 independent experiments. **g**, STAT3 and pSTAT3 expression in HMECs infected with HCMV-FS, HCMV-KM, HCMV-BL, and HCMV-DB strains, as measured by FACS. Histograms represent mean  $\pm$  SD of 3 independent experiments. p-values were determined by Mann-Whitney U test.

**Figure 2.** Appearance of CTH and polyloid giant cancer cells following infection of HMECs with HCMV-DB and HCMV-BL strains. a. Presence of neuron-like elongated cells, displaying multiple nuclei, as observed under an inverted light microscope (1-3) and a fluorescence confocal microscope (4) using DAPI staining. Uninfected HMECs (1), CTH-DB (3 and 4) and CTH-BL (2). b. Presence of dense bodied cells, showing morula-like or blastomere-like structures, as observed under an inverted light microscope (1-6) and a fluorescence confocal microscope (7-8) using DAPI staining. CTH-DB (3, 5, 6, 7) and CTH-BL (1, 2, 4, 8). c. Presence of giant cells, showing granular appearance and blastocyst-like shapes and displaying intense polyploidy, as observed under an inverted light microscope (1-6) and a fluorescence confocal microscope (7-8) using DAPI staining. CTH-DB (1, 5) and CTH-BL (2, 3, 4, 6, 7, 8). Inverted light microscope scale bar represents 100 $\mu$ m; Confocal microscope scale bar represents 10 $\mu$ m.

Elongated spindle-like cells displayed neuron-like shapes, with some cells forming coral-like structures, long microvilli, and filopodia (Figure 2a2-3). Upon observation by confocal microscopy, multiple nuclei were detected within bodies and branches of elongated cells, from where small mononucleated daughter cells were budding (Figure 2a4, red arrow). In parallel, densely packed bodies with smooth edges were also detected (Figure 2b1-6). Some cells exhibited morula-like structure (Figure 2b5), while others were morphologically indistinguishable from blastomeres (Figure 2b1-4). Round cells with short microvilli and some small budding spherical bodies were also present (Figure 2b1, red arrows). Figure 2b7, 8 show asymmetric cell division pattern represented by budding of daughter cells from either mononucleated or multinucleated cells. On the other hand, giant cells appeared to

be hypertrophic, irregular in shape with small apophyses and granular appearance (Figure 2c). Cells displayed ruffle shape (Figure 2c1) and multiple microvilli (Figure 2c2) with some cells exhibiting a blastocyst-like morphology (Figure 2c3). Intensive polyploidization with nuclei displaying irregular contours was detected, parallel to cells displaying a single giant nucleus (Figure 2c7, 8).

The described morphological heterogeneity confirmed the presence of PGCCs in our culture. As the latter are described to undergo the “giant cell cycle”, we monitored by confocal microscopy the fate of infected cells (Suppl. Figure 4). In response to HCMV infection (red arrow), a subset of cells enters the “giant cell cycle” (1), as evidenced by a nucleus size increase, possibly due to endoreplication. Some cells directly bud from giant mononucleated cells (2), whereas others form elongated

ones (3), where DNA migrates horizontally into adjacent cells via the branch of cytoplasm, followed by budding (7). On the other hand, some cells continue endoreplication (4) to generate mononucleated or multinucleated PGCCs (5), followed by depolyploidization, as illustrated by daughter cells budding from multinucleated (6) or mononucleated (7) giant cells. Taken together, our data suggest that infected cells can enter a self-renewal state and grow as PGCCs, followed by depolyploidization, thus fulfilling the steps of the “giant cell cycle”.

#### CTH cells display upregulated EZH2 and Myc expression, EMT traits and stemness

As the deregulation of PRC2 proteins, particularly EZH2, has been linked to the initiation of tumorigenesis, and that Myc is identified as an EZH2 regulator during tumor initiation and progression<sup>23</sup>, we assessed the expression of EZH2, SUZ12 and Myc proteins in CTH cells. EZH2 and Myc expression was upregulated in CTH cells compared to uninfected HMECs (p-value=0.03 and 0.02, respectively; [Mann-Whitney U test]), with a slight increase in SUZ12 expression (p-value=0.11; [Mann-Whitney U test]) (Figure 3a). EZH2, SUZ12, and Myc proteins were positively stained in CTH cells as demonstrated by confocal microscopy imaging (Figure 3b). According to CTH cells subpopulation analysis on the basis of their size (FSC) and ploidy (N) (Figure 3a),<sup>29</sup> PGCCs were shown to highly express EZH2, SUZ12 and Myc proteins, in contrast to small cells (SC). This upregulation was further confirmed by western blot, with a parallel enhanced expression of EZH2, SUZ12, and Myc in CTH cells (p-value=0.07, 0.07 and 0.02, respectively; [Mann-Whitney U test]) (Figure 3c).

PGCCs and SCs undergoing the giant cell cycle are described to have differential expression of proliferation, epithelial, mesenchymal and stemness markers.<sup>27,42</sup> Hence, we assessed the expression of a panel of markers in PGCCs and SCs (Suppl. Figure 5). Compared to uninfected HMECs and SCs, PGCCs are highly proliferative, with high levels of Ki67 Ag, along with a high expression of the mesenchymal marker vimentin and the stemness markers CD49f and CD44, as well CD24, a marker overexpressed in breast cancer (Suppl. Figure 5). EpCAM downregulation was observed in both PGCCs and SCs, compared to uninfected HMECs (Suppl. Figure 5). A slight increase was seen with the epithelial marker E-cadherin in PGCCs, with a remarkable upregulation in SCs (Suppl. Figure 5).

As the acquisition of embryonic-like traits is activated in PGCCs,<sup>38,42</sup> we detected the expression of the embryonic markers Oct4 and Nanog in CTH cells (Figure 4a). This was further confirmed by RT-PCR (Figure 4b) and flow cytometric analysis (Figure 4c), where an upregulation of Oct4, SSEA-4, Nanog, Tra-1-6o, and SOX2 in CTH cells compared to uninfected

HMECs was further demonstrated (p-value=0.03; [Mann-Whitney U test]), with PGCCs expressing the highest level of embryonic stemness compared to SCs (Figures 4d and Suppl. 6). Interestingly, high EZH2 and Myc expression in PGCCs positively correlated with embryonic stemness expression (Figure 4e and f), reinforcing the link between EZH2/Myc upregulation and stemness.

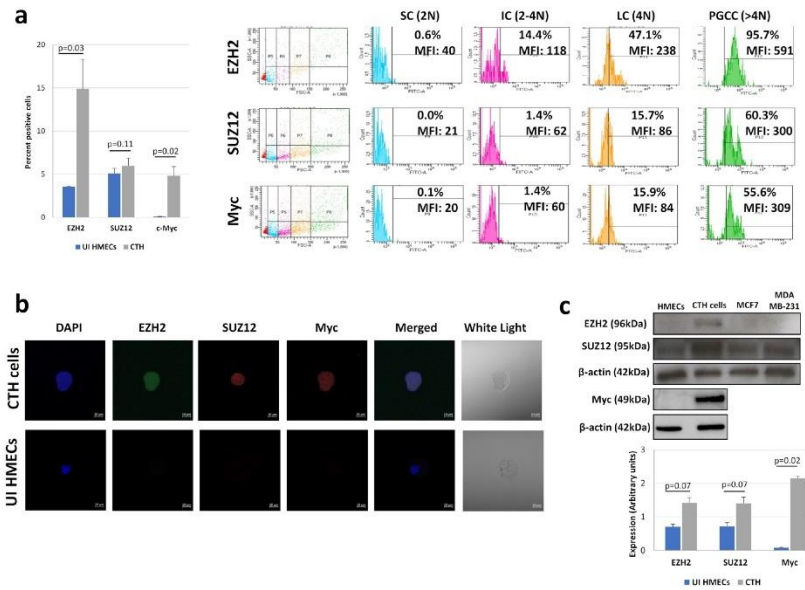

#### EZH2 upregulation regulates proliferation, transformation, stemness, and HCMV replication in CTH cells

Viral presence in CTH cells was confirmed by detecting HCMV pp65 antigen (Figure 5a), which could indicate a potential link between the observed phenotype and HCMV. In addition to pp65 detection, HCMV-DB infected CTH cells were positive for HCMV late antigens (Figure 5a) and IE1 antigen as previously reported.<sup>29</sup>

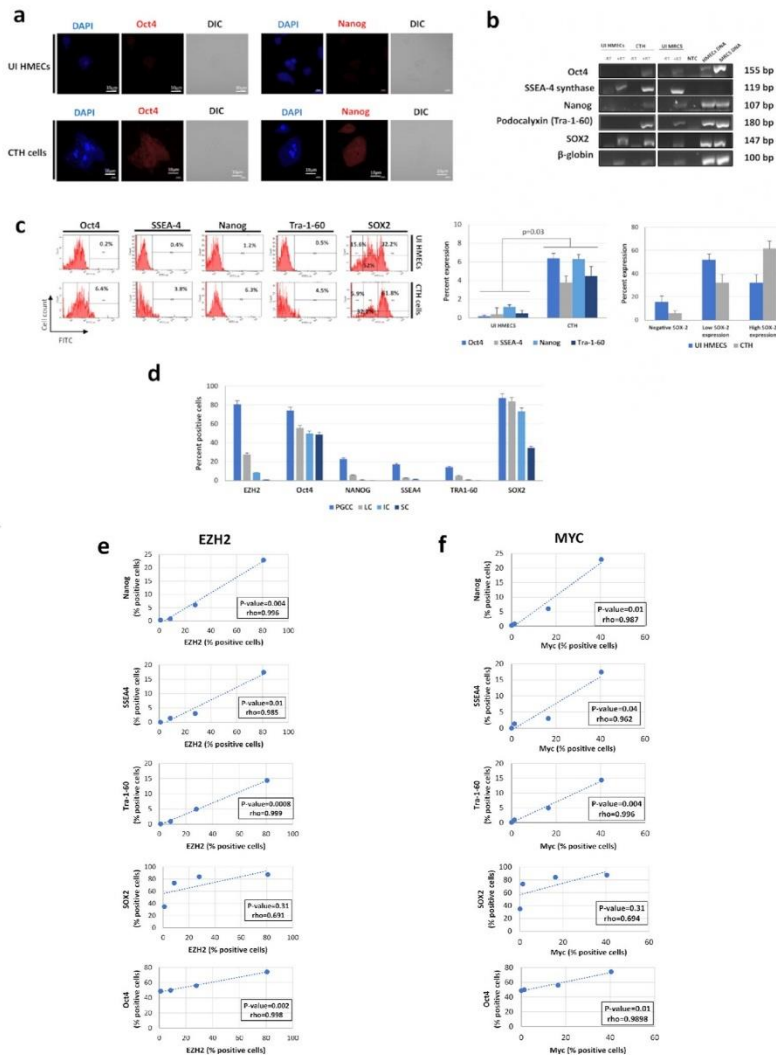

As long non-coding RNAs (lncRNAs), in particular HCMV lncRNA4.9, interact with components of the polycomb repression complex and shape chromatin structure,<sup>25</sup> lncRNA4.9 presence and interaction with EZH2 in CTH cells were confirmed by using conventional PCR and RNA cross-linking immunoprecipitation assay, respectively (Figure 5b and c). An increase in HCMV titer with EZH2 blockage was also detected, compared to untreated CTH cells (p-value=0.03; [Mann-Whitney U test]) (Figure 5d). The viral replication was upregulated in CTH cells treated with EZH2 inhibitors parallel to enhanced H3K4Me3 chromatin mark in the enhancer region of IE gene as measured by chromatin immunoprecipitation (Suppl. Figure 7).

Previously, it has been shown that PRC2 increases breast cancer proliferation and migration, with EZH2 being related to increased tumor cell proliferation<sup>43</sup> and expansion of breast tumor-initiating cells while promoting a stem cell-like phenotype. Upon treatment with the EZH2 inhibitors (EPZ6438 and GSK343), EZH2 blockade significantly decreased the proliferation of treated CTH cells compared to untreated cells as assessed by Ki67 Ag expression levels (p-value=0.02; [Mann-Whitney U test]) (Figure 6a). In addition, EPZ6438 and GSK343 treatment significantly diminished CTH cells colony formation in soft agar (p-value=0.03; [Mann-Whitney U test]) (Figure 6b). Mammospheres formation was described to be inhibited upon EZH2 depletion.<sup>44</sup> Unexpectedly, treatment with EZH2 inhibitors (EPZ6438 and GSK343) did not inhibit mammospheres formation in CTH cells with larger spheres formed with EZH2 inhibitors treatment (Figure 6c). Finally, EZH2, SUZ12, and Myc were highly expressed in HMECs infected with the supernatant which was harvested from CTH-DB cells as demonstrated by confocal microscopy imaging (Suppl. Figure 8).

HCMV-infected cells were used as positive control. DAPI was used for nuclear staining. **b.** RNA4.9 gene presence in CTH-DB cells, as detected by conventional PCR. HCMV-infected HMECs and HCMV-DB genomic DNA were used as positive controls; MRC5 genomic DNA was used as negative control. Histogram represents the ratio of RNA4.9 signal to beta-globin signal as mean  $\pm$ SD of 3 independent experiments. **c.** RNA-Immunoprecipitation of IncRNA4.9 using EZH2 antibody. **d.** Viral titer in supernatant of CTH-DB cells untreated or treated with EZH2 inhibitors GSK343 and EPZ6438, as quantified by IE1 qPCR. Histogram represents mean  $\pm$ SD of 3 independent experiments. p-values were determined by Mann-Whitney U test.

#### PGCCs, EZH2 and Myc upregulation are detected in breast cancer tissues that are HCMV-positive

Previously, PGCCs number in breast cancer was linked to invasion and metastasis.<sup>45</sup> PGCCs with giant or multiple nuclei were present in human breast cancer biopsies, in particular triple negative breast cancer biopsies (Figure 7a). As expected, triple negative biopsies displayed higher tumor grade (p-value<0.001; [Mann-Whitney U test]), tubule formation (p-value=0.02; [Mann-Whitney U test]), nuclear pleomorphism (p-value<0.001; [Mann-Whitney U test]), and mitotic count (p-value=0.0017; [Mann-Whitney U test]) compared to luminal biopsies (Figure 7b). On the other hand, and

compared to healthy biopsies (mean=2.4), tumor biopsies displayed an enhanced EZH2 expression (mean=31, p-value=0.02; [Mann-Whitney U test]), notably in the basal ones (mean=35.8) (Figure 7c). In this latter subset, EZH2 expression was prominent in biopsies harboring HCMV (mean=47.2) (Figure 7c), pointing toward a potential correlation between EZH2 upregulation and HCMV presence. Similar results were observed for Myc expression; Myc was highly expressed in HCMV-positive basal tumors (mean=17.9) compared to luminal ones (mean=2.2) (Figure 7d). High expression levels of EZH2 and Myc were measured in HCMV-positive basal biopsies compared to HCMV-negative basal biopsies

**Figure 6.** EHZ2 inhibitors block CTH cell proliferation, colony formation in soft agar and enhance mammosphere formation. a. Ki-67 Ag expression in CTH untreated and treated with EHZ2 inhibitors (GSK343 and EPZ6438), as measured by FACS. Histogram represents mean  $\pm$ SD of 3 independent experiments. b. Soft-agar assay on CTH cells untreated and treated with EHZ2 inhibitors (GSK343 and EPZ6438). Colony formation was assessed by inverted light microscope observation and quantified by MTT assay. Scale bar represents 100 μm. Histogram represents mean  $\pm$ SD of 3 independent experiments. c. Mammosphere formation assay on CTH cells untreated and treated with EHZ2 inhibitors (GSK343 and EPZ6438). Mammospheres were observed under an inverted light microscope. Scale bar represents 100 μm. p-values were determined by Mann-Whitney U test.

and to all luminal biopsies independent of HCMV status (Figure 7c and d). This was further confirmed by the presence of a strong positive correlation between EZH2 and Myc expression in tumor biopsies, exclusively in the presence of HCMV ( $r=0.929$ ,  $p\text{-value} < 0.001$ ; [Pearson's correlation test]) and particularly in basal samples ( $r=0.914$ ,  $p\text{-value}=0.03$ ; [Pearson's correlation test]) (Figure 7e). Further, PGCC count strongly correlated with EZH2 expression only in tumor biopsies harboring HCMV ( $r=0.750$ ,  $p\text{-value}=0.012$ ; [Pearson's correlation test]), notably in luminal ones ( $r=0.946$ ,  $p\text{-value}=0.015$ ; [Pearson's correlation test]) (Figure 7f). On the other hand, PGCC count strongly correlated with Myc expression in HCMV-positive tissues ( $r=0.733$ ,  $p\text{-value}=0.009$ ; [Pearson's correlation test]), remarkably in basal ones ( $r=0.757$ ,  $p\text{-value}=0.13$ ; [Pearson's correlation test]) (Figure 7g). All in all, two HCMV strains, namely B544 and B693, were detected in biopsies with high expression levels of EZH2 and Myc, and were classified as EZH2<sup>High</sup>Myc<sup>High</sup> basal breast tumors (Figure 7c and d).

#### Isolation of two oncogenic HCMV strains from EZH2<sup>High</sup>Myc<sup>High</sup> basal breast tumors

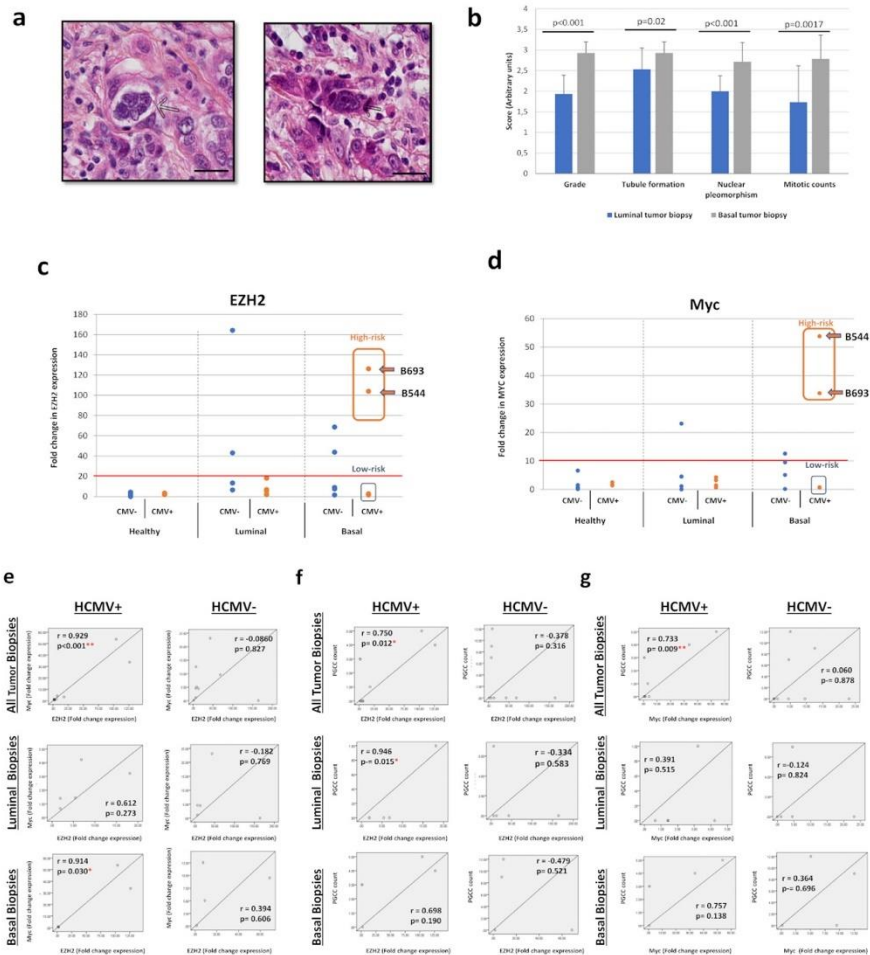

Two HCMV strains, B544 and B693, were isolated from EZH2<sup>High</sup>Myc<sup>High</sup> basal breast tumors by tissue disruption and filtration (Suppl. Figure 9a), and subsequently grown in MRC5 cells, showing a peak of viral load at day 20 and 19 post-infection, respectively (Suppl. Figure 9b). We measured the expression of EZH2, SUZ12, and Myc by FACS analysis, and lncRNA4.9 and IE1 transcripts by RT-PCR assay in HMECs acutely infected with B544 and B693 strains at day 1 post infection. We observed the upregulation of EZH2, SUZ12 and Myc expression in infected cells versus uninfected controls (Figure 8a). In parallel, lncRNA4.9 and IE1 transcripts were detected in HMECs acutely infected with the two strains (Figure 8a). Both B544 and B693 isolates of HCMV transformed infected HMECs toward CTH cells (Figure 8b). Thus, in the culture of CTH-B544 and CTH-B693, at day 105 post-infection, we detected large cells with blastomere-like morphology, numerous small round cells along with mesenchymal cells (Figure 8c). The previously described cell features are similar to that of CTH which were observed in HMEC cultures acutely infected with high-risk oncogenic strains DB and BL (Figure 2); these features could denote transformed cells which undergo different stages of the giant cell cycling. In agreement with the transformation of HMECs infected with B544 and B693 strains towards CTH cells, we observed the formation of colonies in soft agar seeded with HMECs infected with B544 and B693 strains (Figure 8d) indicating that they favor an anchorage-independent growth as previously observed for the high-risk DB and BL strains.<sup>29</sup> Finally, we observed the upregulation of Myc and EZH2 expression in CTH-

B693 and CTH-B544 cells (Figure 8e). Also, we detected lncRNA4.9 transcripts in CTH-B6544 and CTH-B693 cells (Figure 8e). In both CTH-B544 and CTH-B693 cells, we detected the IE1 and late HCMV Ag protein using confocal microscopy (Figure 8f).

#### Discussion

We previously reported the classification of HCMV clinical isolates into low- or high-risk transforming strains.<sup>29,31</sup> Herein, we show that differential expression of Myc, EZH2 and SUZ12 proteins parallels polyploidy induction upon acute infection with low- or high-risk transforming strains. The activation of Myc/EZH2/PGCCs axis upon chronic infection with high-risk strains was further confirmed in CTH cultures, the latter being morphologically heterogeneous upon undergoing the "giant cell cycle", with stemness and EMT traits. Further, CTH cells were shown to harbor HCMV, with a direct physical interaction between HCMV lncRNA4.9 and EZH2, the latter being implicated in proliferation, transformation potential, mammospheres formation and HCMV replication. Breast tumor biopsies were found to harbor PGCCs with enhanced EZH2 expression, a strong positive correlation between EZH2 and Myc expression on one hand, and a high correlation between PGCC count and EZH2/Myc expression on the other hand, exclusively in the presence of HCMV. Finally, two HCMV strains were isolated from EZH2<sup>High</sup>Myc<sup>High</sup> basal breast tumors which acutely transformed infected HMECs toward CTH cells, thereby indicating a direct link between high-risk HCMV strains and basal-like breast cancer.

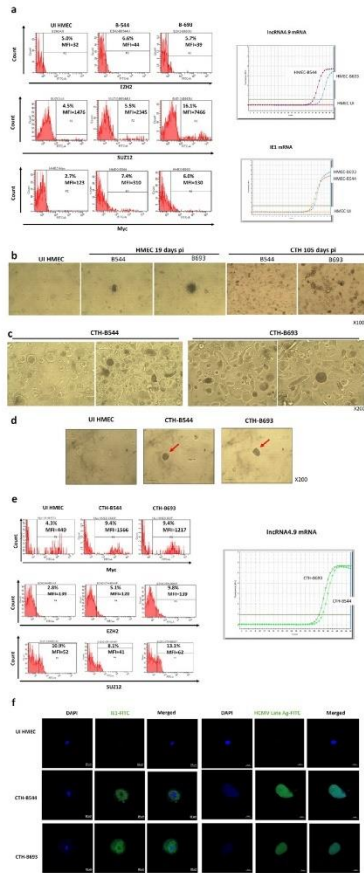

Accumulated evidence highlight Myc and EZH2 as key players in both oncogenesis and stemness.<sup>46–49</sup> Upon acute infection with high-risk strains, a slight activation of Myc, EZH2 and polyploidy induction was noted (Figure 1). The activation of the described axis was further accentuated in CTH cells with a substantial upregulation of Myc and EZH2 proteins (Figure 3), and the appearance of PGCCs in culture (Figure 2). EZH2 overexpression was described to play a crucial role in breast cancer pathogenesis, where it represses early growth response 1 (EGR1) expression, resulting in the inhibition of EGR1-mediated tumor-suppressive signals.<sup>50</sup> Furthermore, EZH2 mediates ribosomal DNA stability via silencing of PHACTR2-AS1, inducing genomic instability and promoting growth and metastasis in breast cancer,<sup>51</sup> in line with the reduction in CTH cells proliferation observed upon EZH2 blockage (Figure 6a). Our results are also consistent with the reported GSK343-induced reduction in glioma cells proliferation.<sup>52</sup> In this sense, one of the molecular mechanisms reported to trigger EZH2 overexpression is through transcriptional regulation by Myc.<sup>23</sup> Indeed, Myc was shown to stimulate EZH2 expression by binding and activating the promoter of the latter,<sup>33,34</sup> by

alternatively repressing its negative regulator miR-26a,<sup>55</sup> or by directly suppressing miR-137, where Myc-miR-137-EZH2 pathway was linked to cisplatin resistance in ovarian cancer.<sup>56</sup> Further, bromodomain-4

protein (BRD4) was shown to positively regulate EZH2 transcription through Myc upregulation.<sup>57</sup> Intriguingly, Myc activation was widely reported in breast cancer progression, particularly in triple-

negative breast cancer and in tumors displaying drug resistant phenotype,<sup>41,47-58</sup> similarly to aggressive medulloblastoma tumors where higher Myc levels were associated with increased EZH2 expression.<sup>59</sup> On the other hand, by uncoupling DNA replication from mitosis, Myc overexpression can induce DNA replication, thus opening the door toward polyploidy.<sup>60</sup> In this context, an intricate relationship between Myc, polyploidy and cancer was demonstrated,<sup>61</sup> with Myc being correlated with nuclear pleomorphism in primary and metastatic renal cell carcinomas.<sup>62</sup> Interestingly, we previously showed that the high-risk HCMV-BL robustly induced Myc expression, along with low p53 levels,<sup>29</sup> which can enhance stem cells replicative potential and reprogramming of progenitors in breast cancer, as Myc was identified as a transcriptional target of p53 in mammary stem cells and is activated upon p53 loss.<sup>63</sup> Besides, HCMV-DB strongly increased pRb expression,<sup>29</sup> with the pRB-E2F pathway being described to regulate the expression of EZH2.<sup>64</sup> Finally, we infected MCF-7 cells with HCMV-DB, BL, and TB40/E strains. We observed the upregulation of Myc expression following infection of MCF7 cells with the high-risk DB and BL strains, but not with TB40/E (Suppl. Figure 10). The three strains slightly upregulated EZH2 and SUZ12 in MCF7 cells (Suppl. Figure 10). Previously, following the infection of HMECs with TB40/E strain, neither a significant activation of the molecular oncogenic pathways was observed in acutely infected HMEC nor CTH cells were detected in culture,<sup>31</sup> especially when compared to the high-risk HCMV-DB and BL strains. Therefore, TB40/E strain should be classified as a low-risk HCMV strain. This data is consistent with the absence of colony formation in soft agar that had been seeded with HMECs infected with TB40/E strain.<sup>31</sup> In addition, the phylogenetic analysis which was done using the whole genomic sequences of several HCMV strains corroborated the similarity of HCMV-DB and BL strains' genomes; genomes of DB and BL strains were dissimilar to the genome of TB40-E strain (Suppl. Figure 11). This emphasizes the hypothesis that high-risk strains DB and BL differentially induce Myc upregulation, and consequently stimulate EZH2 overexpression as well as polyploidy induction, pointing toward the presence Myc/EZH2/PGCCs axis underlying the described results.

Though, the interrelationship between HCMV and EZH2 is further complexed by the detection of HCMV lncRNA4.9 gene in CTH cells (Figure 5b and c). Indeed, cellular lncRNAs such as HOX antisense intergenic

**Panel.** Detection of the lncRNA4.9 transcript in CTH-B544 and CTH-693 cells, as measured by RT-qPCR. **f.** HCMV IE1 protein and HCMV late Ag expression in CTH-B544 and CTH-B693 cells observed by fluorescence confocal microscopy. DAPI was used for nuclear staining.

RNA (HOTAIR) were described to interact with the PRC2 complex in breast cancer, and to increase cancer invasiveness and metastasis.<sup>65</sup> In our present study, it was shown that HCMV-lncRNA4.9 interacts with EZH2 (Figure 5c), which is in line with Rossetto et al. report describing lncRNA4.9 interaction with EZH2 and SUZ12 proteins, suggesting a role of lncRNA4.9 in mediating gene suppression at the MIEP during latency.<sup>25</sup> This is consistent with the increase in viral titer following EZH2 inhibition, possibly due to latency reversal (Figure 5d). In fact, the reactivation of HCMV under EZH2 inhibitors could be explained by at least two distinct mechanisms. First, EZH2 inhibitors could directly block the repressive H3K27 trimethylation in the HCMV promoter/enhancer and favor IE expression followed by viral reactivation.<sup>66</sup> Second, the promoter of the MIEP transcriptional repressor, growth factor independence 1 (GFI1), is controlled by the EZH2-NDY1/KDM2B-JARID2 axis, therefore EZH2 inhibitors might result in an enhanced GFI1 expression which could block viral reactivation.<sup>36</sup> To discriminate between the respective effects of EZH2 on GFI1/MIEP axis and histone methylation (H3K27, H3K4), we performed a ChIP assay. The repressive H3K27Me3 and activator H3K4Me3 marks on the enhancer of the MIEP were studied. The H3K4Me3 mark was shown to be strongly enhanced compared to a very limited increase in the H3K27Me3 chromatin mark on its enhancer at 24 hrs post treatment of CTH-DB (Suppl. Figure 7), consistent with an active transcriptional promoter. Interestingly, although the promoter of the MIEP transcriptional repressor GFI1 is controlled by the EZH2-NDY1/KDM2B-JARID2 axis and EZH2 inhibitors might therefore result in an enhanced GFI1 expression which could block viral replication in human foreskin fibroblasts acutely infected with HCMV,<sup>36</sup> this was not observed in our CTH model. In fact, promoters occupied by GFI1 showed higher levels of the marks associated with active transcription such as H3K4me3.<sup>67</sup> In addition, GFI1 associates with the chromodomain helicase DNA binding protein 4 (CHD4); GFI1/CHD4 complexes occupy active or bivalent promoters as well as active enhancers. These sites have a more closed chromatin configuration when CHD4 is present and a more open chromatin conformation when GFI1 is present.<sup>67</sup> Thus, in CTH cells treated with EZH2 inhibitors, GFI1 might occupy an active transcriptional promoter MIEP with enhanced H3K4Me3 mark or a bivalent promoter, and thereby could stimulate the expression of the IE gene and viral replication. Further, the role of GFI1 on IE transcription and viral replication could depend on the type of HCMV infection (acutely infected cells versus “chronically-infected” CTH cells), the cell type involved (fibroblasts versus epithelial-derived CTH cells) and the differentiation state and lineage commitment of the infected cells.<sup>68</sup> Altogether, the enhanced viral replication observed in CTH cells treated with EZH2 inhibitors

could be mostly explained by the enhanced presence of GFI1 on the MIEP parallel to the enhanced H3K4Me3 rather than the decreased H3K27Me3 chromatin marks (Suppl. Figure 7). Finally, GFI1 may have additional non-transcriptional functions and interacts with a number of proteins involved in DNA repair.<sup>68</sup> An E2F1-mediated DNA damage response contributes to the replication of HCMV<sup>69</sup> making the role of GFI1 even more complex in HCMV replication. The role of GFI1 on HCMV replication definitively needs further studies.

Besides oncogenesis, recent studies have reinforced the importance of EZH2 in maintaining embryonic stemness,<sup>70,71</sup> as well as its implication in cancer stem cells.<sup>72</sup> This evidence correlates with the previously reported up-regulation of the stemness marker CD44 and mammospheres formation in CTH cells.<sup>29</sup> Further, EZH2 was shown to promote breast tumor initiating cells expansion, including mammary stem and luminal progenitor cells,<sup>21,22,73</sup> possibly through the activation of NOTCH1 signaling,<sup>20</sup> prompting the hypothesis that EZH2 facilitates transformation by blocking differentiation.<sup>16</sup> Interestingly, Myc controls the expression of developmental regulators in embryonic stem cells via the upregulation of the PRC2 complex.<sup>74</sup> Myc inhibition depletes cancer stem-like cells in a dose-dependent manner in triple-negative breast cancer.<sup>75</sup> Indeed, EZH2-mediated stemness could underlie not only the maintenance and expansion of PGCCs expressing high degree of embryonic stemness (Figure 4), but also their appearance in culture, as EZH2 expression in astrocytes induced their dedifferentiation toward stem-like cells expressing nestin, SOX2, and CD133.<sup>76</sup> Contrary to the loss and compromised self-renewal of stem cells upon EZH2 deletion,<sup>71,77</sup> we did not observe an inhibition of mammospheres formation upon EPZ6438 treatment; larger mammospheres were detected upon EZH2 blockage (Figure 6c). Indeed, this is in line with some reports describing an expansion of the stem and progenitor cell compartments upon EZH2 loss, coupled to JAK2-V617F axis activation.<sup>78</sup> As EPZ6438 is a selective EZH2 inhibitor,<sup>79</sup> the observed mammospheres expansion could be due to the expression of EZH1, a close homologue of EZH2 that can form an alternative PRC2 complex that partially compensates for the loss of EZH2.<sup>80</sup> To note that, it would be possible that EZH2 depletion in luminal breast cancer cells such as MCF7 cells<sup>44</sup> inhibits stemness and limits mammospheres formation by blocking the appearance of progenitor luminal cells. In this context, given the role of EZH2 in shifting progenitor luminal cells towards basal-like breast cancer cells, its blockade can result in the maintenance of progenitor cells, ultimately increasing mammospheres formation.<sup>81</sup>

A complex interrelation exists between Akt, STAT3 and EZH2. Certainly, STAT3 was described to act as a transcriptional factor that induces EZH2 upregulation by binding to the relative promoter region,<sup>82</sup> justifying

the higher EZH2 expression levels detected in HMECs infected with the high-risk strains compared to the low-risk ones (Figure 1d). In turn, EZH2 overexpression is sufficient for Akt activation, which can mediate breast cancer gene 1 (BRCA1) inhibition, aberrant mitoses with extra centrosomes, and genomic instability.<sup>83</sup> Alternatively, Akt phosphorylation of EZH2 was also reported, where the phosphorylation of the latter may exert pro-tumorigenic functions in a trimethylation-independent manner, as suggested by Xu et al.<sup>84</sup> Phosphorylated EZH2 binds to and methylates STAT3, leading to enhanced STAT3 activity, highlighting the Akt-EZH2-STAT3 axis as a positive regulator of tumor malignancy.<sup>85</sup> Interestingly, E2F8, an atypical transcription factor regulated by STAT3 signaling, was shown to be essential for polyploidization in mammalian cells,<sup>86</sup> potentially participating in the induction of >4N population observed upon infection with the high-risk strains (Figure 1f). We previously described an increase in Akt activation in HCMV-DB and HCMV-BL infected HMECs which is consistent with the observed increase in EZH2 and STAT3 activation.<sup>29,30,87</sup> Detection of a heterogeneous population in CTH cultures (Figure 2) is in line with the previous reports describing the evolution of mononuclear cells upon radio- or chemotherapy treatment into enlarged giant cells with single or multiple nuclei, followed by budding of small daughter cells that actively divide to generate their own progeny cells.<sup>88,89</sup> The detection of asymmetric division in CTH cells confirmed previous reports' findings in which they describe the return of PGCCs into non-polyploid state via the mechanisms of growth and division of simple organisms such as yeasts and other unicellular organisms.<sup>42,90</sup> Indeed, this process of slow self-renewal (Suppl. Figure 4) that was referred to as the "giant cell cycle"<sup>9,38</sup> not only coordinates the morphological dynamics observed in our cultures, but also explains the differential expression of proliferation, stemness and EMT markers between PGCCs and SCs (Suppl. Figure 5). In particular, the activation of embryonic-like stemness in CTH cells (Figure 4) points toward reprogramming and dedifferentiation as we and other researchers previously described.<sup>29,42,91</sup>

Further, we reported the detection of PGCCs in tumor biopsies displaying high EZH2 expression (Figure 7). Our results are in line with other findings describing strong EZH2 expression in the nucleus of invading stem-like PGCCs,<sup>38</sup> as well as in cancer stem-cells population isolated from human breast cancer, xenograft tumor cells, and primary breast tumor cells.<sup>21</sup> It is worth mentioning that the positive correlation detected between PGCC count and EZH2 or Myc expression in tumor biopsies is only established in the presence of HCMV (Figure 7), which indicates a potential role of the latter in the induction and/or maintenance of the observed phenotype. In fact, as our results are in accordance with a described significant positive

correlation between Myc and EZH2 mRNA expression in primary prostate cancer specimens,<sup>23</sup> it has been shown that the infection with Epstein-Barr virus (EBV), a closely related herpesvirus, markedly induced expression of both Myc, and EZH2 mRNA levels in the same experimental model.<sup>92</sup> Since we did not detect EBV in our biopsy samples, this could emphasize a parallel role of HCMV in our model, where further experimental studies are certainly needed to comprehensively understand the exact role played by HCMV in the context of mammary tumors, in particular breast cancer molecular subtypes.

Using distinct methodological approaches, we detected the viral genes IE1 and lncRNA4.9, their transcripts, and most importantly viral proteins such as IE1, pp65, and the late HCMV antigens in CTH cells.<sup>29,31</sup> The detection of early and late viral genes, transcripts and proteins in CTH cells suggested that a lytic cycle is taking place even at a low-level and that the whole genome (or at least most of it) of HCMV high-risk strains might be present in CTH cells. The lytic viral replication could be necessary, even if limited, as well as the viral latency, to maintain/favor the transformed state of CTH cells in culture. In fact, the other two oncogenic herpesviruses, namely EBV and Kaposi's sarcoma-associated herpesvirus (KSHV), require the presence of both lytic and latent viral stages to be oncogenic. Indeed, in addition to the role played by viral latency in EBV and KSHV-induced malignancies, lytic replication might also contribute to EBV-induced oncogenesis and KSHV-induced sarcoma, respectively.<sup>93,94</sup> Further studies are required to clarify the role of HCMV lytic replication and latent dormancy in the described model and the potential contribution of individual lytic or latent HCMV genes to oncogenesis.

Lastly, since EZH2 and Myc have been implicated in tumor initiation, two HCMV strains (HCMV-B544 and HCMV-B693) were isolated from EZH2<sup>High</sup>Myc<sup>High</sup> basal tumors to assess their transforming potential. After infection of HMECs cells with these HCMV isolates, we were able to obtain CTH cells, with morphological features matching those of PGCC, giant cell cycling and the previously described CTH cells obtained with HCMV-DB and HCMV-BL strains.<sup>29-31</sup> The detection of IE1 and HCMV late antigen proteins parallel to upregulated Myc, EZH2 expression and lncRNA4.9 transcript in cultures of CTH-B693 and CTH-B544 cells recapitulates the molecular phenotype observed in CTH-DB and CTH-BL cells. As a result, some high-risk HCMV strains are present in basal breast tumors in which they possess tumor-promoting abilities and therefore are considered as oncogenic strains.

In conclusion, our data indicate that high-risk HCMV strains can induce a polyploid phenotype with a distinctive cell cycle, tumor heterogeneity, epithelial to mesenchymal plasticity and embryonic-like stemness. Our findings highlight the presence of a potential link

between HCMV infection, Myc/EZH2 upregulation and polyploidy induction *in vitro* and in human breast cancer biopsies, supporting the proposed tumorigenesis properties of EZH2 and providing new prospect of using EZH2 inhibitors in the context of breast cancer.<sup>95</sup> A more detailed analysis of PRC2 target genes within CTH cells and their corresponding response to inhibitors may establish new avenues to understand the complex pathogenesis of breast cancer and open the door for targeted therapies in the future.

**El Baba R**, Pasquereau S, Haidar Ahmad S, Diab-Assaf M, Herbein G. Oncogenic and Stemness Signatures of the High-Risk HCMV Strains in Breast Cancer Progression. *Cancers* 2022;14:4271. <https://doi.org/10.3390/cancers14174271>.

Lately, human cytomegalovirus (HCMV) has been progressively implicated in carcinogenesis alongside its oncomodulatory impact. CMV-Transformed Human mammary epithelial cells (CTH) phenotype might be defined by giant cell cycling, whereby the generation of polyploid giant cancer cells (PGCCs) could expedite the acquisition of malignant phenotypes. Herein, the main study objectives were to assess the transformation potential in vitro and evaluate the obtained cellular phenotype, the genetic and molecular features, and the activation of cellular stemness programs of HCMV strains, B544 and B693, which were previously isolated from triple-negative breast cancer (TNBC) biopsies. The strains' sensitivity to paclitaxel and ganciclovir combination therapy was evaluated. A unique molecular landscape was unveiled in the tumor microenvironment of TNBC harboring high-risk HCMV. Overall, the explicit oncogenic and stemness signatures highlight HCMV potential in breast cancer progression thus paving the way for targeted therapies and clinical interventions which prolong the overall survival of breast cancer patients.

**Simple Summary:** Lately, human cytomegalovirus (HCMV) has been progressively implicated in carcinogenesis alongside its oncomodulatory impact. CMV-Transformed Human mammary epithelial cells (CTH) phenotype might be defined by giant cell cycling, whereby the generation of polyploid giant cancer cells (PGCCs) could expedite the acquisition of malignant phenotypes. Herein, the main study objectives were to assess the transformation potential in vitro and evaluate the obtained cellular phenotype, the genetic and molecular features, and the activation of cellular stemness programs of HCMV strains, B544 and B693, which were previously isolated from triple-negative breast cancer (TNBC) biopsies. The strains' sensitivity to paclitaxel and ganciclovir combination therapy was evaluated. A unique molecular landscape was unveiled in the tumor microenvironment of TNBC harboring high-risk HCMV. Overall, the explicit oncogenic and stemness signatures highlight HCMV potential in breast cancer progression thus paving the way for targeted therapies and clinical interventions which prolong the overall survival of breast cancer patients.

**Abstract:** Background: Human cytomegalovirus (HCMV) oncomodulation, molecular mechanisms, and ability to support polyploid giant cancer cells (PGCCs) generation might underscore its contribution to oncogenesis, especially breast cancers. The heterogeneity of strains can be linked to distinct properties influencing the virus-transforming potential, cancer types induced, and patient's clinical outcomes. Methods: We evaluated the transforming potential in vitro and assessed the acquired cellular phenotype, genetic and molecular features, and stimulation of stemness of HCMV strains, B544 and B693, isolated from EZH2<sup>High</sup>Myc<sup>High</sup> triple-negative breast cancer (TNBC) biopsies. Therapeutic response assessment after paclitaxel (PTX) and ganciclovir (GCV) treatment was conducted in addition to the molecular characterization of the tumor microenvironment (TME). Findings: HCMV-B544 and B693 transformed human mammary epithelial cells (HMECs). We detected multinucleated and lipid droplet-filled PGCCs harboring HCMV. Colony formation was detected and Myc was overexpressed in CMV-Transformed-HMECs (CTH cells). CTH-B544 and B693 stimulated stemness and established an epithelial/mesenchymal hybrid state. HCMV-IE1 was detected in CTH long-term cultures indicating a sustained viral replication. Biopsy B693 unveiled a tumor signature predicting a poor prognosis. CTH-B544 cells were shown to be more sensitive to PTX/GCV therapy. Conclusion: The oncogenic and stemness signatures of HCMV strains accentuate the oncogenic potential of HCMV in breast cancer progression thereby leading the way for targeted therapies and innovative clinical interventions that will improve the overall survival of breast cancer patients.

## 1. Introduction

Globally, breast cancer poses a formidable health challenge as it is the most prevalent malignancy accounting for a high number of cancer deaths in women [1]. Breast cancer

consists of a group of heterogeneous diseases driven by a multifactorial etiology involving genetic predisposition, hormones, and environmental factors; viruses are considered indisputable causal factors for nearly 10% of all human malignancies [2].

Human cytomegalovirus (HCMV), a member of the family Herpesviridae subfamily Betaherpesvirinae, is a ubiquitous host-restricted virus with a seroprevalence between 40% and 95% in the adult population [3]. Growing evidence suggests a link between persistent HCMV infection and malignancy [4–7]. Beyond oncomodulation, several studies implicate HCMV as a viral promoter of oncogenesis due to the presence of its nucleic acids and/or proteins in common tumor types [8,9]. Furthermore, HCMV promotes the acquisition of cancer hallmarks such as sustaining proliferative signaling, inducing angiogenesis, evading growth suppressors, avoiding immune destruction and apoptosis, facilitating replicative immortality, activating invasion, and metastasis as well as contributing to therapeutic resistance [8].

Recently, polyploidy, a major hallmark of cancer, was found to be present in approximately 37% of human tumors [10]. Dormant polyploid giant cancer cells (PGCCs) are associated with the induction of quiescence and increased storage capacity through the presence of vacuoles and accumulation of lipid droplets, increased metabolic capacity, and elevated energy production [11–13]. PGCCs could be triggered by radiotherapy, chemotherapy, hypoxia, oxidative stress, hyperthermia, and oncoviruses [14–18]. Beside therapy resistance, PGCCs were associated with metastasis and cancer relapse [18]. A recent study revealed the potential of HCMV in inducing the dedifferentiation of mature HMECs and generating PGCC's phenotype as well as showing a significant correlation between the presence of PGCCs and HCMV in breast cancer biopsies [4].

Between 15% and 20% of all human cancers possess a direct infectious origin [19]. To start with, human papillomavirus (HPV) strains were classified into high- and low-risk strains after being isolated from different lesions. These discoveries were shown to radically alter the tumor diagnosis, prognosis, and prevention approaches [20,21]. Various Epstein-Barr virus (EBV) strains are associated with properties that influence their transforming capacities and the type of induced tumor [22,23]. Additionally, Kaposi's sarcoma-associated herpesvirus (KSHV) isolates were identified in patients of different geographical regions, indicating the importance of these newly isolated strains [24,25] in developing better diagnostic procedures and novel treatment approaches in the context of KSHV-associated malignancies as well as enriching potential vaccine studies [26].

Triple-negative breast cancer (TNBC) comprises 15% of breast cancers globally [27]. Despite its susceptibility to standard chemotherapy, TNBC is highly invasive, has a high relapse tendency, and is associated with a poor overall prognosis [28]. Recently, more significant advances include characterizing the molecular features of TNBC which will maximize the efficacy of certain chemotherapeutic agents and aid in actively exploring novel therapeutic targets [29].

Previous studies demonstrated the ability of HCMV-DB and HCMV-BL strains in transforming primary HMECs into CMV-Transformed HMECs (CTH) cells *in vitro* [4,30]. CTH cells, which are slow self-renewing cells, undergo diverse stages of the giant cell cycle. They were shown to be heterogeneous, generate PGCCs, exhibit dedifferentiation, and display stemness and EMT/MET features [4]. Herein, we originally isolated two HCMV strains, B544 and B693, from TNBC biopsies to assess their transformation potential *in vitro* and evaluate the obtained cellular phenotype, the genetic and molecular features, and the activation of cellular stemness programs. We examined the sensitivity of these strains to paclitaxel (PTX) and ganciclovir (GCV) combination therapy. Further, a specific molecular landscape was disclosed in the tumor microenvironment (TME) of TNBC harboring high-risk HCMV.

## 2. Materials and Methods

### 2.1. Cell Lines and Culture

HMECs (A10565, Life Technologies, Carlsbad, CA, USA), CTH cells, MDA-MB231 as well as MCF7 (Institut Hiscia, Arlesheim, Switzerland), and MRC5 (RD-Biotech, Besançon, France) were cultured as previously described [5]. HCMV-B544 and HCMV-B693 cultures used in this study were maintained for at least 9 months in culture.

### 2.2. HCMV Isolates Growth and Detection

Data corresponding to TNBC biopsies and other HCMV strains were reported previously [5]. To prepare cell-free virus stocks, the two strains were propagated in MRC5 cells for a few passages to avoid losing the ULb' region. Infections of HMECs and MRC5 cells, viral quantification, and replication including assessment of HCMV existence were performed as described previously [4]. Briefly, infection of HMECs or MRC5 ( $1 \times 10^6$ ) cells with the clinical isolates was performed at a multiplicity of infection (MOI) of 1. Cells were incubated at 37 °C for two hours, after which the inoculum was discarded, and the cell monolayer was washed three times using 1X PBS and afterwards covered with fresh medium. For viral quantification, infectious supernatant (cell-free) was harvested, DNA was isolated (EZNA Blood DNA Kit, D3392-02, Omega BIO-TEK) and real-time IE1 quantitative PCR (qPCR) was carried out using a Stratagene Mx3005P thermocycler (Agilent, Santa Clara, CA, USA) and IE1 primers. qPCR was performed using a KAPA SYBR FAST Master Mix (KAPA BIOSYSTEMS, KK4601, Potters Bar, UK); reactions were activated at 95 °C for 10 min, followed by 50 cycles (15 s at 95 °C and 1 min at 60 °C). Results were collected and analyzed using MxPro qPCR software. The primers used are listed in Supplementary Table S1.

### 2.3. Microscopy

CTH cell cultures were monitored and confocal microscopy imaging for HMECs and CTH cells was performed as described previously [5,31]. Primary antibodies targeting IE1, pp65, Myc, Ki67 Ag, Oct4, Nanog, SOX2, and SSEA4 are listed in Supplementary Table S2. Post-staining, the slides were assessed using a 63× oil immersion objective lens with a Carl-Zeiss confocal microscope (Jena, Germany); images were analyzed using ZenBlue Software (Carl-Zeiss Microscopy GmbH).

### 2.4. Soft Agar Colony Formation Assay

Colony formation in soft agar seeded with uninfected HMECs, B544, B693, DB, and BL-infected HMECs, as well as untreated and PTX/GCV-treated CTH cells, was carried out as mentioned previously [5]. MCF7 and MDA-MB231 were used as positive controls.

### 2.5. Tumorsphere Assay

Tumorsphere formation by uninfected HMECs and HMECs infected with HCMV-B544 and HCMV-B693 was evaluated as described in detail previously [6].

### 2.6. Flow Cytometry Analysis

Cells ( $1 \times 10^5$ ) were collected from uninfected HMECs and CTH cells, fixed, permeabilized, and stained as previously reported [5,6]. Cytofluorometric analysis was achieved using a BD LSRFortessa X-20 (BD Biosciences) flow cytometer. FACSDiva software (BD Biosciences) was used for data collection and analysis. Primary antibodies and their corresponding secondary antibodies are detailed in Supplementary Table S2.

### 2.7. Quantitative Reverse Transcription PCR (RT-qPCR)

Reverse transcription was performed as mentioned previously [6]. In brief, RNA was extracted from the biopsies using the EZNA<sup>®</sup> Total RNA Kit I (Omega BIO-TEK, Norcross, GA, USA). Reverse transcription was carried out using the SuperScript IV First-Strand Synthesis kit (Invitrogen, Carlsbad, CA, USA). The expression of markers was assessed by

performing real-time qPCR using a KAPA SYBR FAST Master mix (KAPA BIOSYSTEMS, KK4601) and specific primers according to the manufacturer's protocol. The fold change expression was calculated by adopting the delta-delta Ct method. The primers used are provided in Supplementary Table S1.

### 2.8. CTH Treatment

CTH cells were treated with 12-O-45 tetradecanoylphorbol-13-acetate (TPA) (100 nM, P8139, Sigma-Aldrich, Burlington, MA, USA), ganciclovir (20  $\mu$ M, SML2346 Sigma-Aldrich), and paclitaxel (20 nM, Paclitaxel Arrow 6 mg/mL). Treatment was renewed every day.

### 2.9. Statistical Analysis

All quantitative results are reported as mean  $\pm$  SD of the independent experiments. Statistical analyses were performed using Mann–Whitney test; a  $p$ -value  $\leq$  0.05 was considered significant. Microsoft Excel was used to construct the plots and histogram data.

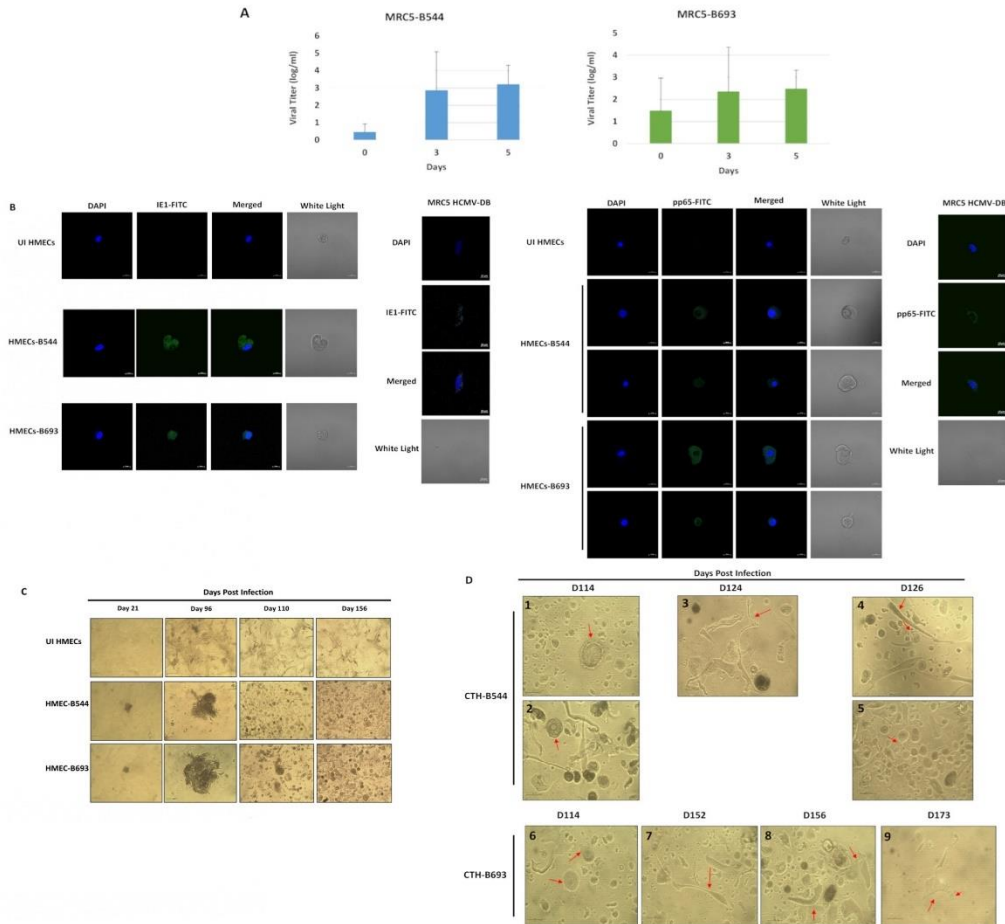

## 3. Results

### 3.1. Growth of Two HCMV Clinical Strains Isolated from TNBC in HMECs and the Emergence of Morphologically Distinct Cells

To assess the cellular environment achieved by HCMV, B544 and B693 were isolated from TNBC biopsies and grown in MRC5 cells, revealing a viral growth at days 3 and 5 post-infection (PI) (Figure 1A). At day 1 post-HMECs infection, HCMV-IE1 and pp65 were detected with confocal microscopy (Figure 1B). HCMV-B544 and B693 promoted the transformation of the infected HMECs toward CTH cells as previously reported [5]. Uninfected HMECs were used as controls which underwent cellular senescence in long-term cultures. At day 110 PI, we detected a wide variety of spheroids and giant cells distributed between round dense cells, flat, and elongated spindle-like cells. Afterwards, lipid droplet-packed cells, multinucleated giant cells, cell budding, and filopodium protrusions were observed in CTH cultures (Figure 1C,D). Hence, this population displayed mesenchymal and fibroblastic-like structures in addition to epithelial and small cells. The above-mentioned detailed cell morphology is close to that of CTH cells which were previously detected in HMEC cultures acutely infected with high-risk BL and DB strains [5]. Thus, the CTH-B544 and CTH-B693 heterogeneous cell population represent transformed and self-renewing cells that are engaged in distinct phases of the giant cell cycle [12,13].

### 3.2. Transformation Capacity of CTH Cells and the Induction of an Oncogenic Environment

To evaluate the transformation of HCMV-B544 and B693 immortalized infected HMECs, cells were seeded in soft agar. Colony formation was detected at day 14 post-seeding in CTH-B544 and CTH-B693 cells ( $p$ -value  $\leq$  0.05) in contrast to uninfected HMECs which showed no changes (Figure 2A). The resulting anchorage-independent growth in CTH cells is a crucial phase in the acquisition of malignancies. With regard to oncogenes, the expression of c-Myc was assessed by performing confocal microscopy imaging where large and elongated CTH cells showed remarkable c-Myc staining compared to uninfected HMECs (Figure 2B). Using flow cytometry, a slightly higher expression of the proliferation marker (Ki67Ag) was detected in CTH-B693 compared to CTH-B544 cells with a limited expression in the uninfected HMECs. Only CTH-B544 and B693 cells were positively stained with Ki67 Ag as detected by confocal microscopy imaging (Figure 3A). On the other hand, a slight increase in the expression of phosphorylated Akt (pAkt-ser473) along with a limited to nonexistent increase in Akt expression levels was shown in all CTH cells compared to uninfected HMECs (Figure 3B and Supplementary Figure S1). Overall, the acquisition of an immortal phenotype in CTH-B544 and B693 cells reflects their transformation potential.

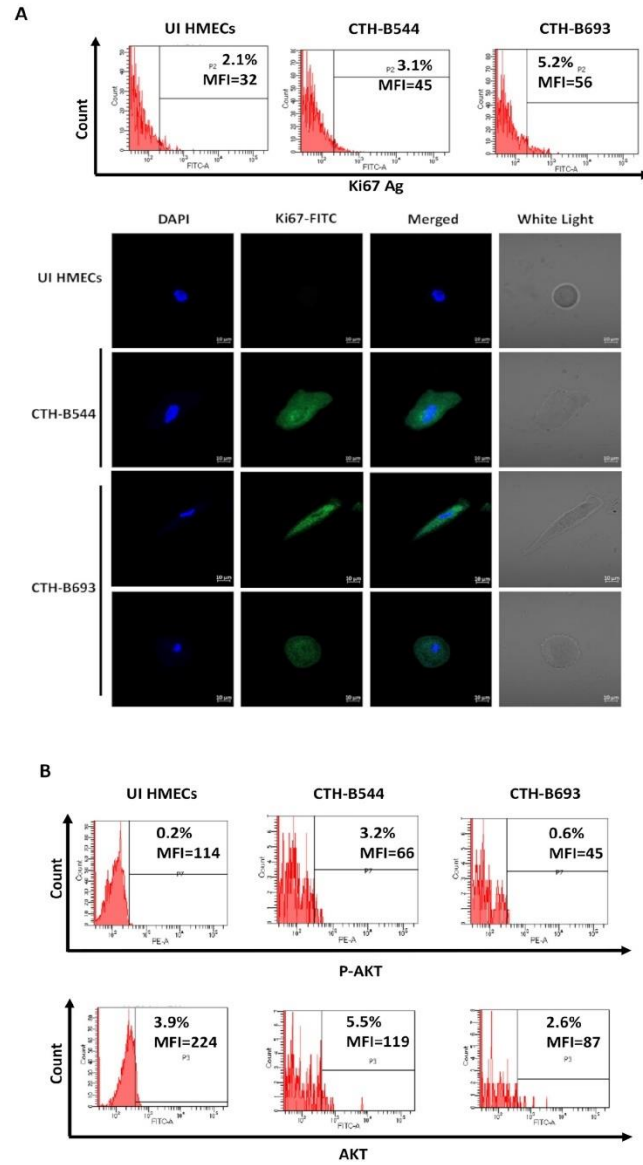

**Figure 1.** Replication of B544 and B693 strains in MRC5 cultures, and the appearance of morphologically distinct cells following the infection of HMECs with these high-risk strains. (A) Time-course of the viral titer in the supernatant of MRC5 infected with the strains HCMV-B544 and HCMV-B693, as measured by IE1-qPCR. (B) Confocal microscopic images of HCMV-IE1 and pp65 staining in HMECs infected with HCMV-B544 and HCMV-B693 (day 1 post-infection). Uninfected HMECs were used as controls. ### 3.3. CTH Cells Promote Embryonic Stemness and Develop an Epithelial/Mesenchymal Hybrid State

When cultured in serum-free tumorsphere medium, CTH-B544 and B693 cells gave rise to mammospheres at day 14 and expressed stemness markers versus uninfected HMECs (Figure 4A). CTH cells revealed a rise in CD44 and CD24 expression when compared to uninfected HMECs (Figure 4B), in line with CTH-DB and BL data (Supplementary Figure S1). Activated expression of the embryonic stem cell markers, SSEA-4 and Nanog, was recognized in CTH-B544, CTH-B693, CTH-DB, and CTH-BL cells by performing flow cytometry (Figure 5A and Supplementary Figure S1) and confocal microscopy imaging (Figure 5B,C). Moreover, CTH-B544 and B693 cells gained embryonic stem-like properties by highly expressing Oct4 and SOX2 as demonstrated by confocal microscopy imaging (Figure 5D,E). Similar to CTH-DB and BL, the newly discovered CTH cells showed an elevated expression of the stemness marker CD49f or Integrin alpha-6, and a limited EpCAM expression (Figure 6 and Supplementary Figure S1). CTH-B544 and B693 as well as CTH-DB and BL cells were positive for both vimentin and E-cadherin staining (Figure 6 and Supplementary Figure S1) thereby signifying their ability to dynamically oscillate between the epithelial-hybrid-mesenchymal spectrum as reported previously in tumors with poor prognosis [32,33]. As a result, CTH-B544 and B693 cells exhibited the following two phenotypes: stemness and hybrid epithelial/mesenchymal phenotypes.

**Figure 3.** CTH proliferation capacities and AKT activation. **(A)** Proliferation assessment by FACS and confocal microscopy; UI HMECs, CTH-B544 and CTH-B693 cells were stained for Ki67 Ag and DAPI. Magnification  $\times 63$ , scale bar 10  $\mu\text{m}$ . **(B)** P-AKT, and AKT expression in UI HMECs and CTH cells, as measured by FACS. Nuclei were counterstained with DAPI; magnification  $\times 63$ , scale bar 10  $\mu\text{m}$ .

#### 3.4. Persistent HCMV Replication in CTH-B544 and CTH-B693 Long-Term Cultures

To determine the sustained HCMV presence, HCMV-IE1 antigen was detected using flow cytometric analysis. IE1 was strongly expressed in CTH-B544 and CTH-B693; uninfected HMECs showed no staining for IE1 (Figure 7A). Using qPCR, we detected HCMV (IE1 DNA) in the supernatant of CTH-B544 and CTH-B693 cultures (Figure 7B). Further, CTH cells were positively stained for HCMV-pp65 antigen versus uninfected HMECs (Figure 7C). CTH cells were treated with TPA to assess latency relevance (Figure 7D,E). Post TPA treatment, the proliferation of CTH-B544 and CTH-B693 cells was promoted (Figure 7D). IE1 detection was elevated at day 1 and day 2 post-treatment in CTH-B544 and CTH-B693, respectively ( $p$ -value = 0.33), and subsequently decreased (Figure 7E).

**Figure 6.** Phenotypic analysis of CTH cells. Detection of a panel of cell markers through FACS staining of CD49f, EpCAM, Vimentin, and E-cadherin in CTH-B544 and CTH-B693 versus UI HMECs. Results are representative of three independent experiments.

Histograms represent the mean data  $\pm$  SD of three independent experiments.

### 3.5. A Specific Molecular Landscape Unveiled in the Tumor Microenvironment of TNBC Harboring High-Risk HCMV

To evaluate the variation in strains' aggressiveness, we compared the transcriptomic profile corresponding to the two high-risk biopsies. The absolute mRNA level of epidermal growth factor receptor (EGFR), cyclin dependent kinase inhibitor 2A (CNDK2A), cyclin D1 (CCND1), SOX2, Oct4, and Nanog was assessed by RT-qPCR. EGFR, a proto-oncogene that enhances cell proliferation and survival, the cell cycle regulator CNDK2A, the proliferation marker CCND1, and the three embryonic markers were overexpressed in biopsy 693 compared to biopsy 544 ( $p$ -value  $\leq 0.05$  for all markers) (Figure 8A). Our results indicated that biopsy 693, from which we isolated the HCMV-B693 strain, is associated with higher tumor aggressiveness and poor prognosis.

**Figure 8.** Distinct responses of CTH cells to paclitaxel/ganciclovir (PTX/GCV) treatment in vitro recapitulates distinct TNBC molecular signatures in vivo. (A) EGFR, CNDK2A, CCND1, SOX2, Oct4, and Nanog mRNA expression was measured by RT-qPCR in TNBC biopsies B544 and B693. Histograms represent the mean  $\pm$  SD of three independent experiments. \*  $p \leq 0.05$ , determined by Mann–Whitney U test. (B) Soft agar seeded with CTH-B544 and CTH-B693 cells treated with PTX (20 nM)/GCV (20  $\mu$ M) combination therapy. Untreated cells were used as negative controls; MCF7 and MDA-MB231 cells were used as positive controls. Magnification  $\times 200$ , scale bar 100  $\mu$ m. (C) Propidium iodide (PI) staining for detection of PGCCs in untreated and treated CTH cells by FACS analysis. (D) Ki67 Ag expression in PGCCs of untreated and treated CTH cells.

### 3.6. Restricting Soft Agar Colony Formation, Controlling PGCCs Count and Proliferation by Paclitaxel and Ganciclovir Therapy

To assess the colony formation in soft agar, CTH cells were treated by PTX/GCV combination therapy to target the oncogenic cellular environment as well as HCMV. Breast cancer cell lines, MDAMB231 and MCF7 were used as positive controls. PTX/GCV treatment of CTH-B544 cells resulted in the disappearance of colonies; however, colony formation was restricted in treated CTH-B693 cells versus untreated cells (Figure 8B). Post therapy, the PGCCs count was reduced by 25% in CTH-B544 while it remained constant in CTH-B693 as measured by FACS (Figure 8C). Further, the proliferation of PGCCs was assessed by Ki67 Ag measurement using flow cytometric analysis; Ki67 Ag expression was reduced in PTX/GCV-treated CTH-B544, but not in CTH-B693 (Figure 8D). Our outcomes revealed that CTH-B544 cells are more responsive to PTX/GCV therapy compared to CTH-B693 cells implying that the latter exhibits aggressive behavior.

## 4. Discussion

To the best of our knowledge, the present study demonstrated the oncogenic transformation and stemness potential of HCMV-B544 and B693 strains that were isolated from TNBC biopsies and indicated a differential treatment response depending on the HCMV strain present in the tumor.

CTH-B544 and CTH-B693 cells are heterogeneous cellular populations that give rise to PGCCs, and display dedifferentiating phenotypes with stemness features as well as hybrid epithelial/mesenchymal phenotypes, resembling the morphological features found in aggressive cancers [13,14,17]. PGCCs formation was promoted in hypoxic environments [12,17]. It is worth noting that hypoxia inducible factor 1 alpha (HIF-1 $\alpha$ ) expression is induced by HCMV infection [34]. In PGCCs, the evaluation of metabolic reprogramming revealed the presence of PLIN4, a perilipin covering the lipid droplets especially in chemoresistant tumors [13]; the Warburg effect [35] and the involvement of the glycolytic pathway were also found to be induced in cancer environments and upon HCMV infection [12].

Myc activation has been widely described in breast cancer progression and can be used as a predictive marker for cancer staging, therapy resistance, and prognosis [36]. It is noteworthy that both B544 and B693 HCMV strains were isolated from EZH2<sup>High</sup>Myc<sup>High</sup>-expressing TNBC, further [5] indicating a potential link between the presence of these HCMV strains and cancer progression. The coupling of c-Myc overexpression with Akt pathway activation observed in CTH cells is in line with previous findings [4]. Moreover, colony formation was detected in CTH-B544 and CTH-B693 cells associated with a high expression level of Ki67 Ag and c-Myc overexpression, thus revealing cellular transformation and their oncogenic potential which is consistent with the previously reported CTH data [4]. Ki67, a prognostic biomarker in invasive breast cancer, is not only required for cell proliferation in tumors but is also strongly linked to tumor initiation, growth, and metastasis [37].

PGCC-bearing CTH cells acquired embryonic-like stemness and an epithelial-mesenchymal hybrid phenotype. Studies have shown that the acquisition of the EMT and stemness properties lead to an increase in the invasiveness and the metastatic potential of cancer cells within tumors [32]. The embryonic stem cells transcriptional network is based on the presence of master pluripotency regulators, Oct4, SSEA-4, SOX2, and Nanog [38]. Besides mammosphere generation, CTH-B544 and CTH-B693 gained a stemness phenotype with increased expression of Oct4, SOX2, and Nanog promoting tumor progression; CTH cells were positively stained for SSEA4 which is associated with EMT and drug resistance [38]. SOX2, Nanog, and Oct4 expression was associated with poor differentiation, advanced cancer stages, and the worst outcomes in breast cancer patients [39].

Studies have implicated CD44 in breast cancer cell adhesion, proliferation, motility and migration, angiogenesis, and metastasis. Limited CD24 expression in breast cancer cells was shown to augment their growth and metastatic potential through a chemokine receptor response [38]. The CD44<sup>high</sup>/CD24<sup>low</sup> phenotype was recognized in CTH-B544 and B693

cells indicating a tumor-initiating phenotype similar to that of the highly tumorigenic breast cancer cells [40]. The existence of an intermediate state between epithelial and mesenchymal phenotypes is considered a hybrid E/M state which is associated with elevated cellular plasticity, migration, stem-cell-like properties, metastatic potential, and therapy resistance [32]. In CTH cells, the co-existence of vimentin and E-cadherin resembled a partial EMT hence ensuring their plasticity while preserving the same tumor-propagating potential [4]. Since in breast tumors CD49f was considered a marker for distant metastasis and recurrence, CD49f+/CD44high/CD24low CTH cells represented an aggressive phenotype which is associated with an increased risk for disease recurrence with poor clinical outcomes [41].

The initiation of KSHV and EBV lytic cycles has been shown to support malignancies driven by the aforementioned oncogenic viruses [42,43]. HCMV persistence was established in CTH cells by detecting IE1 and pp65 throughout long-term cultures [4,5,30]. High-risk strains express immediate-early (IE), early (E), and late (L) viral antigens including IE1 in agreement with a viral lytic cycle following the acute infection of permissive cells such as MCR5 cells. High-risk strains are detected in chronically infected cells, for instance CTH cells in our study, which is in line with the HCMV latency observed in Hodgkin's disease and Non-Hodgkin's lymphoma revealing the latent viral UL138 protein expression [44]. Nonetheless, a dynamic state of latency is recommended by novel transcriptomic studies. Since HCMV develops a complex relationship with the host, to define lytic and latency phases, several studies used the ratio of replicative and latency genes as a phase indicator [45,46]. To further highlight the role of the HCMV-IE1 gene, a study showed the potential of HCMV in regulating stemness in glioblastoma cells by specifically increasing SOX2 and Nestin, thus upregulating stemness and proliferation markers [47].

Studies have suggested that the polymorphism of oncoviruses' strains plays a vital role in explaining their association with distinct pathogenic and tumor properties [22,42]. Certain HPV strains were isolated from invasive cervical cancer biopsies and have thus been acknowledged as oncogenic/high-risk HPV strains [42]. EBV strains cloned and rescued from nasopharyngeal carcinoma (NPC) and gastric carcinomas potentially infect epithelial cells compared to strains originating from infectious mononucleosis (IM) or B lymphoma [22,48]. The existence of diverse strains expressing potential biomarkers and possessing various replication potentials in different tissues and/or cell types explain the distinct oncogenicity [22,23]. The variability of oncogenic and pathogenic KSHV potential was indicated to be dependent on KSHV different subtypes [42]. Overall, discovering distinct viral strains will adjust the different adopted approaches to tumor diagnosis, prognosis, prevention, advanced treatment, as well as therapy monitoring and will enrich potential vaccine studies [21,26,49]. Likewise, the diversity of HCMV strains was validated by our data and the previously published data in which only few clinical HCMV strains conserve the potential to transform HMECs [6] and fit with a "blastomere-like" model of oncogenesis [4]. When HCMV-B544 and B693 were isolated from IE1/Myc/Ki67/EZH2-positive TNBC biopsies [5], the findings revealed a phenotype similar to the already described HCMV-DB and BL phenotype.

On the transcriptomic level, biopsy 693 overexpressed EGFR, CNDK2A, CCND1, SOX2, Oct4, and Nanog. It is known that EGFR promotes TNBC progression through JAK/STAT3 signaling [50], CNDK2A drives TNBC tumorigenesis [51], CCND1 has a prognostic significance in TNBC [52], and the three embryonic markers correlate with stemness, metastasis, tumor relapse, and poor clinical outcomes of TNBC [53]; therefore, we propose that biopsy 693 maintains a tumor signature that is associated with an aggressive behavior which predicts poor clinical outcome.

A study revealed the potential of combining GCV with certain chemotherapeutic agents to suppress EBV-positive NPC tumor growth [54]. In HPV-infected cervical cancer cells, cidofovir and cisplatin inhibited cellular proliferation, reduced E6 protein expression, and restored the activity of p53 [55]. A third study showed the effectiveness of anti-herpetic drugs, GCV and cidofovir, as single therapies or in combination with chemotherapy in

treating KSHV-associated primary effusion lymphoma (PEL) [56]. Based on our results, the heterogeneity of HCMV strains including their distinct behavioral aspects had a major impact on CTH cells' response post-therapy. CTH-B544 cells were therapy sensitive whereas CTH-B693 cells displayed an aggressive behavior with lower sensitivity to PTX/GCV combination therapy. Generally, isolating distinct HCMV strains from tumors that possess potential prognostic biomarkers and behave differently depending on their own heterogeneity and various cell types may improve the diagnostic process and treatment options, provide effective follow-up strategies, and may be essentially pertinent in breast cancer pathophysiology and other adenocarcinomas, particularly of poor prognosis.

## 5. Conclusions

Our outcomes originally revealed the oncogenic and stemness potential of two HCMV strains, namely B544 and B693 where HCMV generated PGCCs, displayed dedifferentiating phenotypes with stemness features as well as hybrid epithelial/mesenchymal phenotypes. Large-scale experiments are highly encouraged to further validate our findings. Meanwhile, the presented data provides new insights into the oncogenic role of HCMV in breast cancer progression, thereby uncovering novel targeted therapeutic approaches and assisting in the development of advanced clinical interventions.

Human cytomegalovirus (HCMV) is a common herpesvirus infecting a significant portion of the population. While it often causes mild symptoms, HCMV can trigger strong immune responses and persist for life. In individuals with weakened immune systems, such as those with AIDS or transplant recipients, HCMV can lead to severe diseases. Immunosenescence, associated with aging and inflammation (inflammaging), has received increased attention. HCMV is closely linked to accelerated aging of the immune system and age-related diseases, contributing to mortality, reduced vaccine efficacy, serious illnesses, and cancer, particularly in the elderly. HCMV can both initiate and worsen immunosenescence, and its reactivation, involving different viral cycles, adds to its genetic diversity. In addition to its oncogenic role, the immune-privileged tumor microenvironment plays a significant part in tumor progression. Understanding the interplay between HCMV, immunosenescence, and cancer could lead to novel therapeutic approaches, particularly for challenging cancers in older individuals.

### Abstract

Human cytomegalovirus (HCMV), whose genome is around 235 kb, is a ubiquitous human herpesvirus that infects between 40% and 95% of the population. Though HCMV infection is commonly asymptomatic and leads to subtle clinical symptoms, it can promote robust immune responses and establish lifelong latency. In addition, in immunocompromised hosts, including individuals with acquired immunodeficiency syndrome (AIDS), transplant recipients, and developing fetuses it can lead to severe diseases. Immunosenescence, well-defined as the alterations in the immune system, is linked mainly to aging and has been recently gathering considerable attention. Senescence was characterized by an elevated inflammation and hence considered a powerful contributor to “inflammaging” that is measured mainly by tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), interleukin-6 (IL-6), and C-reactive protein (CRP) levels as well as latent viral infections, for instance, cytomegalovirus (CMV). Inflammaging resulted in a senescence-associated secretory phenotype (SASP). HCMV is markedly associated with accelerated aging of the immune system as well as several age-associated diseases that accumulate and subsequently deteriorate the immune responses, thus have been linked to mortality, declined vaccine efficacy, serious diseases, and tumors in the elderly. HCMV triggers or exacerbates immunosenescence; on the other hand, the weakened immune responses and inflammaging favor viral reactivation and highlight the role of HCMV in aging as well as viral-associated tumors. HCMV reactivation resulting in sequential lytic and latent viral cycles could contribute to HCMV genomic variability. Besides the oncomodulatory role and transforming capacities of HCMV, the immune-privileged tumor microenvironment has been considered the main element in tumor progression and aggressiveness. Therefore, the interplay between HCMV, immunosenescence, and cancer will aid in discovering new therapeutic approaches that target HCMV and act as immune response boosters mainly to fight cancers of poor prognosis, particularly in the elderly population.

## Introduction

Human cytomegalovirus (HCMV) belongs to the  $\beta$ -herpesvirus family and is a prevalent human pathogen infecting 40% to 95% of the world's population [1]. Following primary infection, cytomegalovirus (CMV) possesses the capacity to induce both lytic and latent infections to establish lifelong persistence in human hosts [2]. The clinical course of HCMV infection is widely variable, it depends on the age and is highly influenced by the immune fitness of the host. While the immunocompetent healthy individuals are asymptomatic, the congenitally infected infants could be symptomatic at birth and suffer long-term neurologic sequelae [3]. However, over time pronounced changes occur in the human immune system, known as immunosenescence. These age-related changes decrease immune protection and have been linked to mortality, decreased vaccine responsiveness, cardiovascular diseases, and cancer in the elderly [4, 5]. Importantly, while some studies implicate HCMV in driving immunosenescence and disease risk, others suggest it enhances immune function [6, 7]. Recently, HCMV has been reported to induce oncomodulation and even oncogenesis in some cases [2]. In this review, the role of HCMV in driving immunosenescence and its impact on oncogenesis were highlighted.

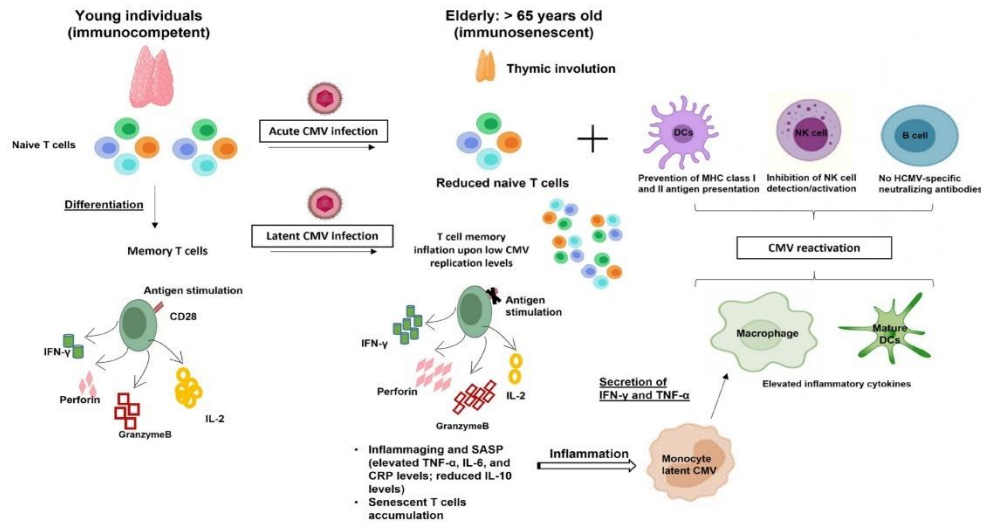

## Concepts and hallmarks of immunosenescence

Immunosenescence is a normal physiologic process in which immune system function slowly changes with age. In fact, immunosenescence is regulated by many factors including aging, particularly the degeneration of the thymus resulting in a decrease of the T cell population and decrease of CD8<sup>+</sup> naive T cells, one of the main manifestations of immunosenescence [8]; as well the inflammation which produces senescence-associated secretory phenotype (SASP) wherein aging cells secrete soluble factors such as growth factors, cytokines, chemokines, and extracellular matrix inducing several senescence-related diseases, including various malignancies [9] in addition to the overlooking of intrinsic and extrinsic factors of the immune system [10]. Moreover, the characterization of the hallmarks of immunosenescence is essential, especially for understanding its impact on the disease risk and tumor progression. With aging, the cytotoxic effect of immune cells as well as the expression of interferon  $\gamma$  (IFN- $\gamma$ ) and cytotoxic molecules such as granzyme B and perforin decrease [11, 12]. In addition, memory T cells which differentiate from naive T cells upon primary antigenic stimulation play a crucial role in the adaptive immune system and enable a robust immune response over the human lifespan. Nevertheless, pronounced age-associated changes occur in the composition of T cell populations (naive *versus* memory cells). Despite the increased number of memory cells during early life, it shows senescent changes after 65 years [13]. One of the most prominent markers of T cell senescence is the loss of the costimulatory molecule CD28 and the accumulation of highly differentiated effector memory T cell [CD27<sup>-</sup>CD28<sup>-</sup>CD57<sup>+</sup> killer cell lectin-like receptor G1 (KLRG1)<sup>+</sup>], which are hallmarks of immunosenescence [14]. Another hallmark of senescent T cells is telomerase shortening [15]. It should be noted that, in the process of immunosenescence, there is remodeling of mature natural killer (NK) cells and reduced expression of the activated receptors which may affect the immune monitoring effect of NK cells in the elderly [16]. Age-related modifications also occur in naive/memory B cell subsets. Indeed, in the elderly, there is a reduction of naive B cells, accompanied by the expansion of memory B cells that show a senescence-associated phenotype [17]. While the functions of dendritic cells (DCs) such as antigen presentation, endocytosis, and IFN production are reduced in elderly individuals [18], the phagocytic ability of neutrophils decreases [19]. Aged macrophages reduce their functional activity leading to the accumulation of unphagocytosed debris, increased senescent-associated markers, increased inflammatory cytokine production, reduced autophagy, and a decrease in Toll-like receptor (TLR) expression [20].

## HCMV infection driving immunosenescence

Following primary infection, HCMV has the capacity to induce both lytic and latent infection to establish lifelong persistence in human hosts. Despite the extensive innate and adaptive response elicited by HCMV infection during both lytic and latent infection, the virus develops diverse immune evasion strategies to alter the host immune recognition [21]. The clinical presentation of HCMV infection is highly influenced by the immune response of the host during distinct life stages. In healthy immunocompetent hosts, viral reactivation which occurs throughout life induces the establishment of immune memory leading to the control of viral replication. However, in immunocompromised hosts, the loss of CMV-specific CD4<sup>+</sup>CD8<sup>+</sup> T cells favors uncontrolled viral replication and dissemination leading to serious clinical diseases and even death [22]. In addition, long-term HCMV persistence will modulate the immune system composition and function even in healthy HCMV-infected individuals (Figure 1). Many epidemiologic studies on aging indicate that HCMV seropositivity is associated with immunosenescence and increased mortality in the elderly [23, 24]. Moreover, HCMV seropositive older individuals have a reduced response to vaccination [25]. Reactivation of HCMV triggered in severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infected patients exacerbates the risk of coronavirus disease [26]. Although, the link between HCMV and immunosenescence request more investigation, HCMV persistence is thought to be a driver of immunosenescence in humans [7]. It was postulated that inflation of HCMV-specific T cells during viral persistence compromised host immunity. In HCMV-infected elderly individuals, the CD8<sup>+</sup> T cells response to HCMV antigens constitutes 50% of the entire memory CD8<sup>+</sup> T cells compartment in peripheral blood, while around 30% of total circulating CD4<sup>+</sup> T cells can be HCMV responsive [27]. The majority of this terminally differentiated inflationary HCMV-specific CD8<sup>+</sup> T cell subset has a typical age-related senescent T cell phenotype [CD57<sup>+</sup>CD28<sup>-</sup> C-C motif chemokine receptor 7 (CCR7)<sup>-</sup>], lacking CD28 expression which is a major characteristic of T cell aging [28]. This finding is supported by the fact that this large population of HCMV-specific CD8<sup>+</sup>CD28<sup>-</sup> T cells is absent in seronegative elderly individuals [29]. Moreover, in elderly hosts, impairment of T cell immunity is also linked to memory inflation in HCMV infection. Despite the diverse CD8<sup>+</sup> T cells repertoire to recognize different viral epitopes soon after HCMV primary infection, this diversity starts to decrease with age often manifested as large clonal expansions of cells of limited antigen specificity together with a marked shrinkage of the T cell antigen receptor repertoire [7]. In elderly hosts, more than 25% of total CD8<sup>+</sup> T cells show a specific response to an individual immunodominant HCMV epitope such as p65 tumor suppressor protein (p65) and immediate early 1 (IE1) [30]. This limited diversity of HCMV-specific T cell clones during memory inflation may affect the immune protection to novel and vaccine antigens through decreased T cell receptors (TCRs) diversity in the elderly and thereby exposing them to the risk of life-threatening diseases [31]. Additionally, in older adults, most inflationary CD4<sup>+</sup> T cells induce T-helper 1 (Th1) responses by producing IFN- $\gamma$  which explains the poor humoral responses seen in the elderly [32]. Although HCMV has a more immunologic impact on memory T cells than naive T cells, it also alters naive T cells. Thus, mainly and exclusively in older subjects with elevated anti-CMV antibody titers, there is a significant decrease in CD4<sup>+</sup> naive T cells parallel to an absolute increase in effector/effector memory CD4<sup>+</sup>CD8<sup>+</sup> T cells [33].

Moreover, cell exhaustion, another form of T cell dysfunction, can arise during chronic infection which is often associated with inefficient control of persisting infections due to the loss of proliferative potential, decreased cytotoxicity, impaired cytokines secretions, and high expression of several inhibitory receptors [programmed death 1 (PD1), KLRG1, and CD57]. HCMV-specific CD8<sup>+</sup> T cells are characterized by a low proliferative capacity and expression of senescent markers such as KLRG1 and CD57. These cells are not totally exhausted since they are still highly cytotoxic and produce Th1 cytokines in response to viral replication [31]. It's worth mentioning that HCMV infection leads to the accumulation of functional exhausted cells that could accelerate immunosenescence in immunocompromised and immunosuppressed individuals [34].

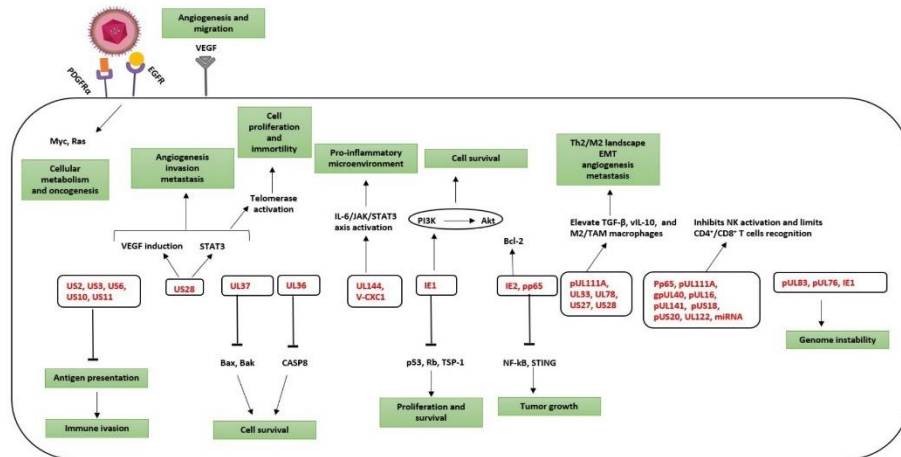

**Figure 1.** HCMV-induced immunosenescence. Acute and chronic HCMV infections modulate the host immune system resulting in naive T cell pool depletion and memory inflation, respectively which further drive/accelerate immunosenescence. The weakened immune responses and inflammaging favor HCMV reactivation which is the key to the accumulated HCMV-specific immune responses. IL-2: interleukin-2; TNF- $\alpha$ : tumor necrosis factor- $\alpha$ ; CRP: C-reactive protein; MHC: major histocompatibility complex

## Immunosenescence—a key player in cancer

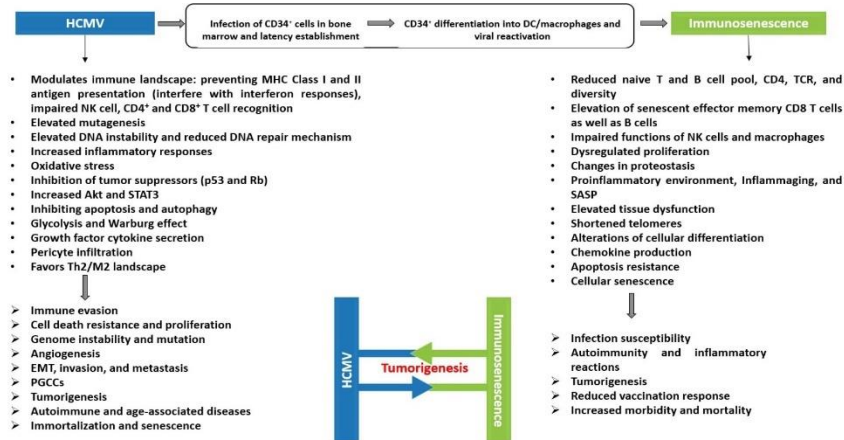

Due to the increased rates of mortality and morbidity of various tumors with age, cancers are generally defined as aging diseases. The immunosenescence features and mechanisms were described as an important player in the tumoral process resulting in a high-risk of tumors in elderly groups [35]. Immunosenescence in the tumorigenesis process reflects the senescence of both innate (NK cells and macrophages) and acquired immune cells (B cells and T cells) affected on one side by the age-related change and the other side by the factors of the tumor microenvironment (TME). In acute myeloid leukaemia (AML) in elderly patients, NK cells harbor diminished levels of several activating receptors that contribute to impairing NK function and thereby favoring disease progression and decreased survival [36]. Age-modified changes in tissue-specific macrophages and neutrophils cause chronic low inflammation that is associated with a macrophage pro-tumorigenic phenotype [19]. Cytotoxic T lymphocytes (CTLs) are critical in eliminating tumor cells as well as virally infected cells. Thus, alterations of CTL function observed during aging could favor both viral infection and cancer. In patients with HCMV-positive glioblastoma multiforme (GBM), the signs of immunosenescence in the CD4<sup>+</sup> T cells compartment are associated with poor prognosis which may reflect the activity of HCMV [37]. Aging can also alter the TME. Thus, the increased presence of tumor-associated macrophages (TAMs) and tumor-derived  $\gamma\delta$  regulatory T cells (Tregs) in TME has been reported to decrease both innate and adaptive immunity; TAMs produce cytokines that promote T cell inactivation and inhibition of DCs activity thus increasing cancer cell proliferation [38, 39]. In hypoxic TME, tumor-derived cyclic adenosine monophosphate (cAMP) activates DNA damage and induces T cell senescence [40]. Similarly, glucose deprivation triggers DNA damage and activates the p38 pathway leading to cell cycle arrest and inhibition of T cell proliferation [41]. Moreover, the TME oncogenic stress activates signaling pathways including nuclear factor- $\kappa$ B (NF- $\kappa$ B), p38, CCAAT/enhancer binding protein  $\beta$  (C/EBP $\beta$ ), and mechanistic target of rapamycin complex 1 (mTORC1) which play a role in regulating T cell SASP [42]. Furthermore, in aging, secretion of SASP molecules, such as IL-6, IL-8, and IL-10 in TME favors tumor progression through an inflammaging mechanism [43, 44]. Finally, HCMV favors immunosenescence with decreased immune defenses and inflammaging that could trigger viral reactivation from latency and further supports its role in aging as well as viral-driven malignancies.

## Oncomodulatory and oncogenic properties of HCMV

Besides HCMV-induced immunosenescence, presented evidence reveals HCMV presence in numerous solid tumors [45, 46]. HCMV proteins have been found in 90–100% of breast, ovarian, colon, and prostate tumors, in sarcomas as well as in neural-derived tumors such as neuroblastoma, glioblastoma, and medulloblastoma [47]. Taking into account the broader concept of cancer hallmarks, the TME and cancer progression are considered essential oncomodulatory mechanisms relating tumor initiation to viral infections caused by oncoviruses [48]. HCMV mediates both oncomodulation and oncogenesis (Figure 2) [49]. During HCMV infection, the virus expresses viral gene products possessing potential transforming capacities and activating specific molecular pro-oncogenic pathways. HCMV key products involves IE1, IE2, unique short 28 protein (pUS28), viral IL-10 (vIL-10), unique long 76 protein (pUL76), pUL97, pUL82, pUS2, pUL16, 65-kDa tegument protein (pp65), pUL36, pUL37x1, and long non-coding RNA4.9 (lncRNA4.9) [49]. Early HCMV proteins regulate main cellular factors, for instance, retinoblastoma protein family, p53, cyclins, Wnt, phosphoinositide 3-kinase (PI3K)/protein kinase B (Akt), and NF- $\kappa$ B, hence affecting the cell cycle, differentiation, cellular proliferation, apoptosis, and metabolism [50–52]. HCMV-unique short 28 (US28) stimulates signaling pathways that are well-known to interfere with proliferation as well as survival, migration, angiogenesis, and inflammation [53–56]. pp65 tends to incapacitate the intrinsic cellular immune responses [57]. By expressing CMV IL-10 (cmvIL-10), HCMV displays a potent immunosuppressive effect thereby promoting the maturation of protumoral M2 macrophages TAM [58]. Thus, HCMV can entirely promote the steps of classical hallmarks of cancer through the expression of many gene products [49]. Furthermore, a direct oncogenic outcome was revealed by a few HCMV strains, namely, high-risk strains [59], that could promote cellular stress, polyploid giant cancer cells (PGCCs) generation, stemness, and epithelial-to-mesenchymal transition (EMT) plasticity explaining the appearance of aggressive tumor phenotypes, particularly adenocarcinomas, having poor prognosis, metastasis, therapy resistance, and relapse [46, 60]. HCMV-DB and BL, isolated high-risk clinical strains, displayed oncogenic potential in human mammary epithelial cells (HMECs) and replicated in epithelial cells with the interchange of lytic and latent viral cycles promoting the appearance of CMV-transformed HMECs (CTH cells) [60–62]. Two additional high-risk HCMV strains, namely biopsy 544 (B544) and B693, recently isolated from enhancer of zeste homolog 2 (EZH2)<sup>high</sup> Myc<sup>high</sup> triple-negative breast cancer (TNBC) biopsies revealed oncogenic and stemness potential [63, 64]. EZH2 was identified as a downstream target for HCMV-induced Myc upregulation upon HMECs infection with high-risk HCMV strains [64]. In GBM tissues harboring HCMV, EZH2 overexpression was detected [65]. EZH2 is overexpressed in PGCCs highlighting the presence of a potential link between HCMV infection, Myc/EZH2 upregulation, and PGCC generation [64]. Hence, this evidence suggests that some HCMV strains may not only possess an oncomodulatory role but in a certain cellular context, it unveils direct tumor-promoting strategies. Besides the transforming capacities of HCMV, the TME has increasingly been recognized as a key element in tumor progression and metastasis [2]. Restricted immune control against HCMV will favor the productive viral infection in the immune-privileged TME thereby supporting a stem-cell-like state of cancer cells and promoting cancer aggressiveness [66, 67]. HCMV reactivation in M1 macrophages promotes an M2/TAM shift, thus driving the neoplastic progression [21, 68]. Tumor cells evade immune responses promoting EMT, metastasis, and relapse. Therefore, in tumor cells, the association of cellular machinery and viral immune evasion mechanisms may give rise to an environment that enhances limited HCMV replication and triggers cancer cells to evade immune surveillance revealing the bidirectional association between cancer cells and HCMV [21, 69]. Persistent HCMV infection markedly alters the host immune system and has been suggested to trigger or exacerbate age-associated diseases as well as immunosenescence (Figure 3) [70, 71].

**Figure 2.** HCMV from oncomodulation to oncogenesis. Activation of specific molecular pathways that are implicated in oncomodulation and cellular transformation. Oncomodulation, which favors the growth and spread of tumor cells, as well as oncogenesis are mainly targeted by HCMV gene products (in red). PDGFR $\alpha$ : platelet-derived growth factor receptor  $\alpha$ ; EGFR: epidermal growth factor receptor; VEGF: vascular endothelial growth factor; STAT3: signal transducer and activator of transcription 3; JAK: Janus kinase; TGF- $\beta$ : transforming growth factor  $\beta$ ; UL37: unique long 37; V-CXC1: viral chemokine (C-X-C motif) ligand 1; gpUL40: glycoprotein unique long 40; miRNA: microRNA; STING: stimulator of interferon genes; TSP-1: thrombospondin 1; CASP8: caspase 8; Bcl-2: B-cell lymphoma 2; Bax: Bcl-2-associated X protein; Bak: Bcl-2 homologous antagonist/killer; Rb: retinoblastoma protein

**Figure 3.** The interplay between HCMV-induced immunosenescence and oncogenesis. A scheme showing the potential association between HCMV, immunosenescence, and tumorigenesis. Persistent HCMV infection fulfills all the cancer hallmarks and is associated with enhanced aging of the immune system. Immunosenescence and inflammaging play a substantial role in the pathogenesis of several serious diseases in the elderly. Both players, HCMV and immunosenescence, have been associated with high mortality rates, chronic diseases, and tumors

## Conclusions

HCMV infection and immunosenescence in clinical conditions such as organ transplantation, cancer, immunodeficiency, as well as autoimmune and inflammatory illnesses, support the concept that HCMV can affect their progression by inducing immunosenescence. In return, immunosenescence favors HCMV reactivation from latency in an inflammatory microenvironment (inflammaging). Viral reactivation will trigger

HCMV-driven oncomodulation by low- and high-risk HCMV strains, and could also promote the initiation of tumorigenesis, particularly by high-risk HCMV strains, thus directly favoring the appearance of tumors especially adenocarcinoma and glioblastoma in an immunocompromised TME with immunosenescence and inflammaging traits. A better understanding of the complex interaction between HCMV, immunosenescence, and tumors will open new perspectives to explore novel therapeutic approaches that will reverse immunosenescence and boost the immune system to fight viral infections, especially HCMV, and tumor development in the elderly.

## Abbreviations

Akt: protein kinase B  
CMV: cytomegalovirus  
DCs: dendritic cells  
EMT: epithelial-to-mesenchymal transition  
EZH2: enhancer of zeste homolog 2  
HCMV: human cytomegalovirus  
HMECs: human mammary epithelial cells  
IE1: immediate early 1  
IFN- $\gamma$ : interferon  $\gamma$   
IL-6: interleukin-6  
KLRG1: killer cell lectin-like receptor G1  
NF-kB: nuclear factor-kB  
NK: natural killer  
p65: p65 tumor suppressor protein  
PGCCs: polyploid giant cancer cells  
pp65: 65-kDa tegument protein  
pUL76: unique long 76 protein  
pUS28: unique short 28 protein  
SASP: senescence-associated secretory phenotype  
TAMs: tumor-associated macrophages  
Th1: T-helper 1  
TME: tumor microenvironment  
UL37: unique long 37  
US28: unique short 28

**El Baba R**, Pasquereau S, Haidar Ahmad S, Monnier F, Abad M, Bibeau F, et al. EZH2-Myc driven glioblastoma elicited by cytomegalovirus infection of human astrocytes. *Oncogene* 2023;42:2031–45. <https://doi.org/10.1038/s41388-023-02709-3>.

Increasing evidence suggests that human cytomegalovirus (HCMV) may have oncogenic potential, particularly in malignant gliomas. Notably, the presence of the EZH2 and Myc genes correlates with the severity of gliomas. This study provides the first experimental proof that HCMV can reprogram mature human astrocytes, leading to the creation of CMV-Elicited Glioblastoma Cells (CEGBCs) with traits resembling glioblastoma cells. HCMV mimics the cellular and molecular processes associated with transformation and invasion, with CEGBCs exhibiting spheroid formation and invasiveness. Glioblastoma multiforme (GBM) biopsies were characterized by elevated EZH2 and Myc expression, with a strong positive correlation when HCMV was present. Eleven clinical HCMV strains were isolated from GBM tissues, transforming astrocytes into CEGBCs with increased EZH2 and Myc expression. These CEGBC-derived spheroids displayed invasive potential and were responsive to treatment with an EZH2 inhibitor, ganciclovir, and temozolomide. This research establishes a model for HCMV-induced glioblastoma and underscores the significance of Myc and EZH2 in astrocytic brain tumor pathophysiology, offering potential avenues for novel therapeutic strategies.

Mounting evidence is identifying human cytomegalovirus (HCMV) as a potential oncogenic virus. HCMV has been detected in malignant gliomas. EZH2 and Myc play a potential oncogenic role, correlating with the glioma grade. Herewith, we present the first experimental evidence for HCMV as a reprogramming vector, straight through the dedifferentiation of mature human astrocytes, and generation of *CMV-Elicited Glioblastoma Cells* (CEGBCs) possessing glioblastoma-like traits. HCMV counterparts the progression of the perceived cellular and molecular mechanisms succeeding the transformation and invasion processes with CEGBCs involved in spheroid formation and invasiveness. Glioblastoma multiforme (GBM) biopsies were characterized by an elevated EZH2 and Myc expression, possessing a strong positive correlation between the aforementioned markers in the presence of HCMV. From GBM tissues, we isolated HCMV clinical strains that transformed HAs toward CEGBCs exhibiting upregulated EZH2 and Myc. Spheroids generated from CEGBCs possessed invasion potential and were sensitive to EZH2 inhibitor, ganciclovir, and temozolomide triple therapy. HCMV clinical strains transform HAs and fit with an HCMV-induced glioblastoma model of oncogenesis, and supports the tumorigenic properties of Myc and EZH2 which might be highly pertinent in the pathophysiology of astrocytic brain tumors and thereby paving the way for new therapeutic strategies.

*Oncogene* (2023) 42:2031–2045; <https://doi.org/10.1038/s41388-023-02709-3>

## INTRODUCTION

Glioblastoma multiforme (GBM), a subtype of adult diffuse glioma, is a primary central nervous system (CNS) tumor presumed to arise from neuroglial stem cells or their progenitors in the subventricular zone [1, 2]. There has been a recent paradigm shift, with increasing reliance on molecular information for diagnostic classification and prognostication within gliomas, as seen in the most recent World Health Organization (WHO) classification of CNS tumors [2]. Despite the molecular evolution of GBM, it continues to be an incurable disease with poor survival.

Cancer etiological factors are assorted into genetic or environmental risk factors of which viruses are estimated to contribute to 20% of all cancer cases [3]. Human cytomegalovirus (HCMV) is a ubiquitous pathogen belonging to *Herpesviridae* family that is often detected in cancer patients [4]. It exhibits a broad cellular tropism providing an advantageous platform for efficient viral proliferation and inter-host transmission, with a prominent role of blood monocytes in viral dissemination [5]. The establishment of viral reservoirs and latency in monocytes, tissue macrophages, and myeloid lineage CD34<sup>+</sup> hematopoietic progenitor cells could further promote disease progression. Potential interrelation between HCMV and cancer has been explored and oncomodulation paradigm was used to explain HCMV genome and/or antigens detection in a multitude of malignancies including breast cancer, colorectal, prostate, and GBM [4, 6–8]. HCMV infects

neural stem/progenitor cells, and human astrocytes [9–12]. Going beyond oncomodulation, previous studies demonstrated HCMV ability to induce the transformation of human embryonal lung fibroblasts [13] and human mammary epithelial cells (HMECs) in vitro [7, 14, 15]. Although HCMV DNA and antigens, especially IE1, have been detected in GBM tissue [16], there is no conclusive evidence about HCMV oncogenicity in GBM, and the mechanisms by which the virus might contribute/induce oncogenesis remain elusive.

Being the enzymatic subunit of polycomb repressive complex 2 (PRC2), enhancer of zeste homolog 2 (EZH2) is a histone-lysine N-methyltransferase responsible of transcriptional silencing. EZH2 was shown to expand the stem cell pool and the tumor-initiating cells in glioma, breast and prostate cancer, hence enhancing accelerated initiation, metastasis and growth [17–19]. It was identified as a downstream target of Myc oncogene, the latter coordinately regulating EZH2 through transcriptional and post-transcriptional mechanisms during tumor initiation and disease progression [20]. EZH2 was shown to be recruited to the major immediate early promoter (MIEP) in CD14<sup>+</sup> monocytes where HCMV establishes latent infection in vivo [21]. Further, EZH2 was demonstrated to be overexpressed in GBM tissues harboring HCMV [22]. EZH2 was overexpressed in polyploid giant cancer cells (PGCCs) [23, 24], the latter being also triggered by HCMV infection in breast cancer [15] which points toward a

potential link between HCMV, PGCCs, and EZH2. Myc has been found overexpressed in GBM; its expression correlates with glioma grade where 60–80% of GBM reveal elevated Myc levels [25]. In glioma cells, EZH2 knockdown depleted Myc expression [19]. Further, Myc direct transcriptional regulation by EZH2 may establish a new mechanism underlying glioma cancer stem cell maintenance [17].

Although the mainstay of treatment for GBMs is surgery, followed by radiation and chemotherapy especially temozolomide (TMZ), new therapeutic strategies are needed. The development of checkpoint inhibitors has opened new possibilities to fight GBM [26]. In addition, some EZH2 inhibitors have been proven efficient in some poor prognosis cancers [27]. The detection of HCMV in GBM biopsies could suggest the use of anti-HCMV therapies [28]. Immunotherapies directed against HCMV antigens [29, 30] seem to show that curtailing HCMV infection contributes to a positive outcome in GBM patients.

To assess the HCMV oncogenic potential in human astrocytes (HAs), HAs were infected with HCMV-DB and BL clinical strains that were previously isolated in our laboratory and shown to elicit the transformation of human mammary epithelial cells [7, 24]. Herein, we screened the two HCMV clinical strains for their transforming potential and analyzed for the first time the molecular and cellular features of CMV-elicited glioblastoma cells, CEGBCs, which appeared in long-term cultures. Moreover, we assessed the impact of TMZ, the antiviral drug GCV, and EZH2 inhibitor (GSK 343) *in vitro* within this glioblastoma model. Given the stated EZH2 oncogenic functions, we aimed to evaluate the presence of a potential link between the triad of HCMV, CEGBCs and EZH2, as well as the potential interrelation with Myc in the context of glioblastoma carcinogenesis. This was complemented by deciphering the morphological and phenotypic characteristics of CEGBCs and the potential implication of Myc and PRC2 proteins in both CEGBCs and GBM biopsies. In the latter, we isolated eleven clinical HCMV strains that displayed oncogenic, stemness, and invasiveness features when cultivated on HAs with enhanced EZH2/Myc expression that could be curtailed by combination therapy including TMZ, GCV, and EZH2 inhibitors.

## RESULTS

### HCMV clinical isolates permissively infect HAs inducing increased Myc and EZH2 expression

The cellular environment induced by HCMV infection was assessed by studying the tropism of DB and BL high-risk HCMV strains (Fig. 1) as well as KM and FS low-risk HCMV strains (Supplementary Fig. 1) to HAs. HCMV-DB and BL strains replicated in HAs with a burst of viral growth (6 logs for DB and 3 logs for BL) followed by occasional blips (Fig. 1a and Supplementary Fig. 2). Acute infection was then confirmed through immediate early gene (IE1), pp65, and the late HCMV antigens detection (Fig. 1b, c and Supplementary Fig. 1). In addition, IE1 and early/late gene (UL69) transcripts were detected in HAs infected with HCMV-DB and BL compared to controls (Fig. 1d). At day 3 post-infection, Myc was overexpressed in HAs-DB and BL compared to controls ( $p$ -value = 0.09), mostly in HAs-DB. Elevated EZH2 expression was detected in HAs-DB and BL compared to uninfected HAs ( $p$ -value = 0.02) (Fig. 1e). Myc and EZH2 transcripts were detected in HAs-DB and BL compared to controls (Fig. 1f). Lower apoptosis levels were recognized with the two strains (Fig. 1g) in line with Akt and pAkt-Ser473 upregulation as confirmed by western blot and FACS, particularly with HCMV-DB (Fig. 1h). In contrast to the high-risk DB and BL strains, the low-risk FS and KM strains did not elicit any of the above-mentioned behavior (Supplementary Fig. 1). Taken together, a Myc<sup>High</sup> EZH2<sup>High</sup> molecular profile was observed with both high-risk strains, preferentially with HCMV-DB.

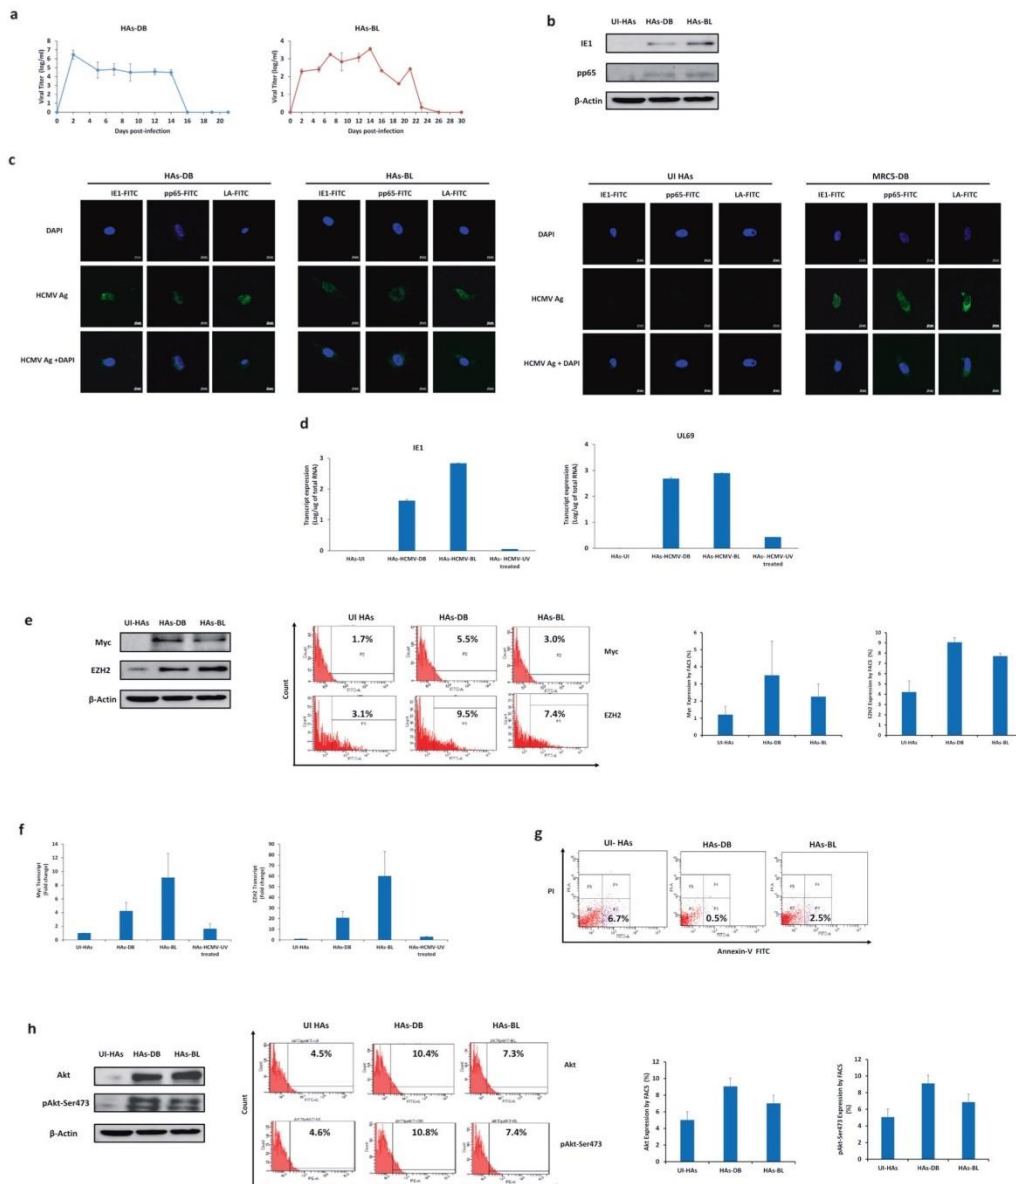

### Emergence of a glioblastoma-like phenotype with CEGBCs in HAs chronically infected with high-risk HCMV strains that display dedifferentiation, embryonic stemness, PMT traits and spheroid-forming capacity

In contrast to the low-risk HCMV strains that didn't allow long-term replication in HA cultures and were senescent (Supplementary Fig. 1), HAs infected with HCMV-DB and BL were maintained in culture for an extended period of time (Supplementary Fig. 2). Around day 80–90 post-infection, dense cellular aggregates appeared in HCMV-BL and DB cultures with invasive-like cells irradiating from the main cellular structures resembling the formerly described "go or growth" phenotype of glioblastoma cells [31] (Fig. 2a, b). Cells with a glioblastoma-like phenotype were termed "CMV-Elicited Glioblastoma Cells" or CEGBCs similar to the previously reported "CMV-Transformed Human mammary epithelial cells" or CTH cells [7, 15].

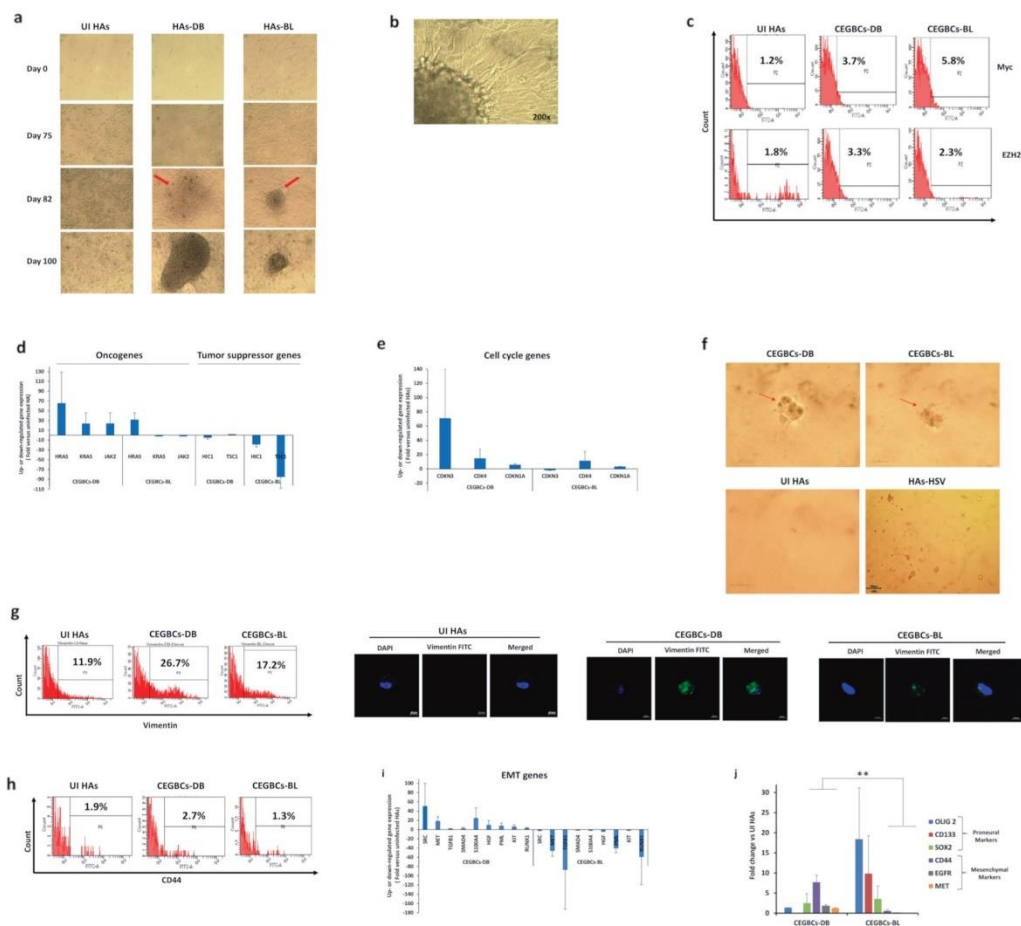

We next assessed the protein expression of EZH2 and Myc in CEGBCs in which increased expression levels were observed compared to controls (Fig. 2c). CEGBCs characterization was achieved by assessing oncogenes, tumor suppressor genes and cell cycle genes. Oncogenes and cell cycle genes were mainly upregulated in CEGBCs-DB; however, tumor suppressor genes were down-regulated mostly in CEGBCs-BL (Fig. 2d, e). CEGBCs-DB and BL were seeded on a soft agar to evaluate their tumorigenic potential and colony formation was detected; uninfected HAs and HAs infected with herpes simplex virus (HSV) showed no colony formation (Fig. 2f). Primary GBM experiences the subtype switch during relapse, shifting from the proneural (PN) subtype to the mesenchymal (MES) one namely the proneural-mesenchymal transition (PMT), thus acquiring a therapy-resistant phenotype [32]. With regards to PMT markers, vimentin was elevated mostly in CEGBCs-DB, and to a lesser extent in CEGBCs-BL (Fig. 2g). CD44, a widely accepted marker for cancer stem cells and a mesenchymal marker regulating both stemness and epithelial-mesenchymal plasticity, was shown to be predominantly upregulated in CEGBCs-DB (Fig. 2h). EMT genes were mostly upregulated in CEGBCs-DB compared to CEGBCs-BL (Fig. 2i). CEGBCs-DB were shown to be close to the transcriptome profile of mesenchymal glioblastoma (mGB) whereas CEGBCs-BL expressed more PN traits (mesenchymal markers:  $p$ -value (CEGBCs-DB:CEGBCs-BL) = 0.002; proneural markers:  $p$ -value (CEGBCs-DB:CEGBCs-BL) = 0.06) (Fig. 2j). Taking into account the proteomic and transcriptome data, CEGBCs-DB mostly displayed a mesenchymal phenotype compared to CEGBCs-BL. High levels of SOX2, Oct4, and SSEA4 were detected in CEGBCs (Fig. 3a and Supplementary Fig. 5a, b). Hence, the identified stemness features in CEGBCs indicated their relevance to glioblastoma stem cells (GSCs). Assessing the spheroid formation potential of CEGBCs, spheroids were generated 24–48 hours post-seeding; no spheroid formation was detected in HAs infected with HSV (Fig. 3b). Nestin and IE1 were concomitantly expressed in CEGBCs-DB and BL spheroids (Fig. 3c).

### CEGBCs productively infected with high-risk HCMV display invasiveness

CEGBCs from spheroids readily invaded astrocyte scaffolds, by aligning along and intercalating between astrocytes and penetrating all scaffold layers as measured by nestin detection. After 7 days, nestin was present in the spheroids' core and invasive part; cells were IE1 and nestin-positive. HCMV-IE1 was predominantly located in the spheroid core and present in the individual cells detaching from the core (Fig. 3d). Uninfected HAs expressed GFAP in the absence of nestin (Supplementary Fig. 13). PGCCs and neural progenitor cell (NPC)-like cells, positive for nestin and IE1, were also present (Fig. 3e, f); supernatants were positive for HCMV-IE1 indicating ongoing viral replication (Supplementary Fig. 8). Further, using a 3D collagen-invasion assay, invasiveness was noticed for CEGBCs-DB and to a lesser extent for CEGBCs-BL as measured by the invasion area (Fig. 3g, h); the protrusions'

Data are represented as mean  $\pm$  SD of two independent experiments.

number and length were also recorded (Supplementary Fig. 7). Within the CEGBCs-DB cultures, the majority of invading cells adopted a neural progenitor-like phenotype with a round small cell body and a long leading process characterized by high cell motility (Supplementary Fig. 9, left panel). Cellular heterogeneity occurred among the invasive cells with random morphology in which low motility cells co-existed with highly motile cells (Supplementary Fig. 9). Three mechanisms of invasiveness were

detected in CEGBCs-DB and BL cultures as recently reported [33] (Supplementary Fig. 10a–c). Filopodia and lamellipodia were also observed (Supplementary Fig. 10d).

#### Detection of lncRNA4.9/EZH2 and HOTAIR/EZH2 complexes in CEGBCs cultures

HCMV latency in CEGBCs cultures was established by IE1 expression that was observed at day 1 post-TPA treatment

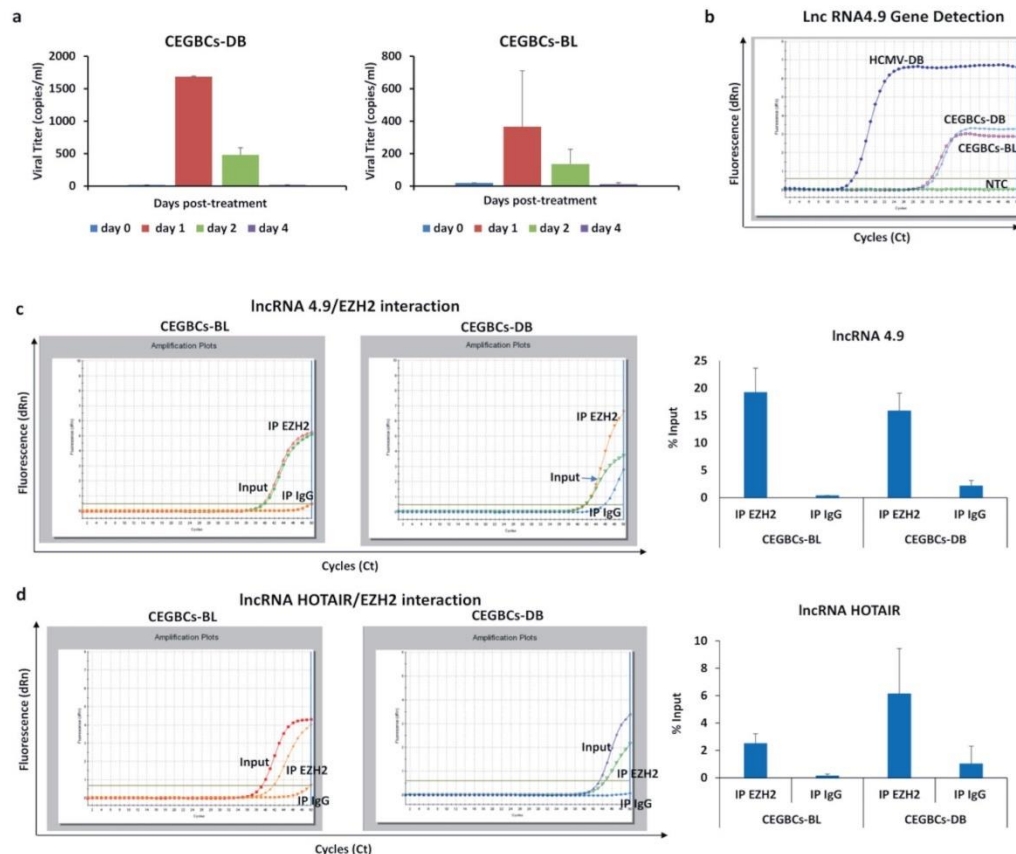

(Fig. 4a and Supplementary Fig. 6) parallel to the detection of HCMV gene (lncRNA4.9) (Fig. 4b). In agreement with the presence of the lncRNA4.9 gene in EZH2-expressing CEGBCs, we observed the interaction of HCMV lncRNA4.9 and cellular lncRNA HOX antisense intergenic RNA (HOTAIR) transcripts with

EZH2 using RNA CLIP assay (Fig. 4c, d). Cellular lncRNA HOTAIR transcript, reported as a poor prognostic factor in cancers [34] was detected particularly in the EZH2 immunoprecipitated samples corresponding to CEGBCs-DB compared to CEGBCs-BL (Fig. 4d).

#### Upregulation of EZH2 and Myc in HCMV-positive GBM tissues

To further decipher the role of HCMV and EZH2-Myc pathway *in vivo*, we analyzed 37 GBM biopsies (MGMT promoter methylated  $n=17$  and MGMT promoter unmethylated  $n=20$ ) for the presence of HCMV as well as EZH2 and Myc expression. Tumor biopsies displayed an enhanced EZH2 and Myc expression in both

MGMT promoter methylated and unmethylated tissues, particularly in MGMT promoter unmethylated ones (Fig. 5b). HCMV was detected in all GBM samples (100%) (Supplementary Table 3). In all GBM biopsies, there was a statistically significant strong correlation between Myc and EZH2 expression (Fig. 5c). A significant strong correlation was found between HCMV presence (IE1 gene)

**Fig. 5** HCMV detection as well as EZH2, and Myc expression in glioblastoma biopsies. **a** Glioblastoma multiforme tissue was stained using HES; magnification x40, scale bar 25 μm. **b** Scattered plots showing Myc, and EZH2 expression in individual methylated, and unmethylated HCMV-positive GBM biopsies. Mean values are indicated. **c** Correlation test between Myc and EZH2 expression in all GBM biopsies, methylated, and unmethylated HCMV-positive GBM biopsies. and Myc/EZH2 expression in unmethylated GBM biopsies ( $r = 0.690$ ,  $p$ -value = 0.001;  $r = 0.589$ ,  $p$ -value = 0.006; respectively) (Fig. 5d). In unmethylated GBM biopsies, HCMV presence (UL69 gene) strongly correlated with Myc/EZH2 expression ( $r = 0.507$ ,  $p$ -value = 0.02 and  $r = 0.544$ ,  $p$ -value = 0.01, respectively) (Fig. 5e). On the other hand, a weak to moderate correlation was detected between HCMV presence and Myc/EZH2 expression in methylated GBM biopsies (Fig. 5d, e).

#### Isolation of oncogenic HCMV strains from GBM tumors

Among the thirty-seven GBM biopsies, eleven GBM biopsies were considered for HCMV isolation. Eleven HCMV-GBM strains were isolated from MGMT promoter methylated ( $n = 4$ ) and MGMT promoter unmethylated ( $n = 7$ ) GBM tumors by tissue disruption and filtration, and were subsequently grown in MRC5 cells showing a peak of viral load (1–3 log) around day 20 post-infection (Fig. 6a and Supplementary Table 4). Following HAS infection with the eleven HCMV-GBM strains, we detected cell clusters with irradiating low and high motility cells displaying a neural progenitor-like phenotype (Fig. 6b) parallel to the sustained viral replication confirmed by FACS (Fig. 6c) and IE1 gene detection by qPCR (Fig. 6d). Viral transcripts (IE1 and UL69) were detected in HAS infected with methylated and

unmethylated HCMV-GBM strains compared to uninfected HAS (Fig. 6e). Upregulated Myc and EZH2 proteins and transcripts were detected in HAS infected with methylated and unmethylated HCMV-GBM strains, unlike uninfected HAS (Fig. 6f–h and Supplementary Table 4). All HCMV-GBM isolates transformed HAS as measured by soft agar colony formation assay ( $p$ -value (UI HAS: HCMV-GBM) = 0.02;  $p$ -value (UI HAS: HCMV-GBM-M) = 0.04,  $p$ -value (UI HAS: HCMV-GBM-UM) = 0.03) (Fig. 6i).

Spheroids were generated 24–48 hours post-seeding the HAS infected with the clinical HCMV-GBM strains ( $p$ -value (UI HAS: HCMV-GBM) = 0.02;  $p$ -value (UI HAS: HCMV-GBM-M) = 0.04,  $p$ -value (UI HAS: HCMV-GBM-UM) = 0.03) (Fig. 7a). High SOX2 levels were detected in spheroids generated from the eleven HCMV-GBM strains (Fig. 7b and Supplementary Table 4). Nestin and IE1 were concomitantly expressed in spheroids generated from all HCMV-GBM strains (Fig. 7c). Spheroids generated from the HCMV-GBM strains did not express GFAP unlike uninfected HAS (Supplementary Fig. 13). Further, a 3D collagen-invasion assay was performed to evaluate the invasiveness potential of the spheroids generated from HCMV-GBM strains (Fig. 7d). The lncRNA4.9 gene was detected in CEGBCs derived from HCMV-GBM strains (Fig. 7e). Viral lncRNA4.9 and cellular lncRNA HOTAIR transcripts were detected in the EZH2

immunoprecipitated samples corresponding to CEGBCs derived from all HCMV-GBM strains, mostly from MGMT promoter unmethylated HCMV-GBM strains, using RNA CLIP assay ( $p$ -value (UI-HA9:GBM) = 0.03;  $p$ -value (UI-HA9:GBM-M) = 0.07;  $p$ -value (UI-HA9:GBM-UM) = 0.04) (Fig. 7f).

**EZH2 inhibitor, TMZ, and GCV tritherapy curtails CEGBCs growth**

Although TMZ is known as the first-choice chemotherapeutic agent in glioblastoma, TMZ resistance often becomes a limiting factor in effective glioblastoma treatment [35, 36]. Herein, we

evaluated EZH2 inhibitor GSK343, GCV and TMZ efficacy as single therapies, as well as bi- or tri-combination therapy on CEGBCs-DB, BL, and GBM spheroids (Fig. 8). TMZ reduced spheroids' size by 23% only in CEGBCs-BL cultures, unlike CEGBCs-DB which displayed more mesenchymal traits ( $p$ -value<sub>(CEGBCs-DB:CEGBCs-BL)</sub> = 0.03). GCV reduced the spheroids' size by 21% and 24% in CEGBCs-DB and BL, respectively ( $p$ -value<sub>(CEGBCs-DB:CEGBCs-BL)</sub> = 0.35). On the other hand, GCV/TMZ combination therapy lead to a 27% size reduction of CEGBCs-BL spheroids, meanwhile having a very limited effect in CEGBCs-DB in which the spheroids' size was reduced by 9% ( $p$ -value<sub>(CEGBCs-DB:CEGBCs-BL)</sub> < 0.01) (Fig. 8a). Spheroids of CEGBCs-DB and BL were treated by GSK343, GSK343/GCV, GSK343/TMZ, and GSK343/GCV/TMZ. CEGBCs-DB were resistant to mostly all therapies except the triple therapy ( $p$ -value<sub>(CEGBCs-DB:CEGBCs-BL)</sub> = 0.06) unlike CEGBCs-BL that were mainly responsive to GSK343/TMZ ( $p$ -value<sub>(CEGBCs-DB:CEGBCs-BL)</sub> < 0.001) and triple treatment ( $p$ -value<sub>(CEGBCs-DB:CEGBCs-BL)</sub> = 0.06) (Fig. 8a). Under triple therapy (GSK343/GCV/TMZ), spheroids' size was reduced by around 90% in CEGBCs-DB and BL at day 10 post-treatment ( $p$ -value<sub>(triple therapy: TMZ)</sub> = 0.02) (Fig. 8b). Spheroids' size was reduced by around 60% with all the eleven HCMV-GBM strains at day 10 post-triple treatment (GSK343/GCV/TMZ) ( $p$ -value<sub>(triple therapy: TMZ)</sub> < 0.001) (Fig. 8c), similar to that reported for DB and BL strains.

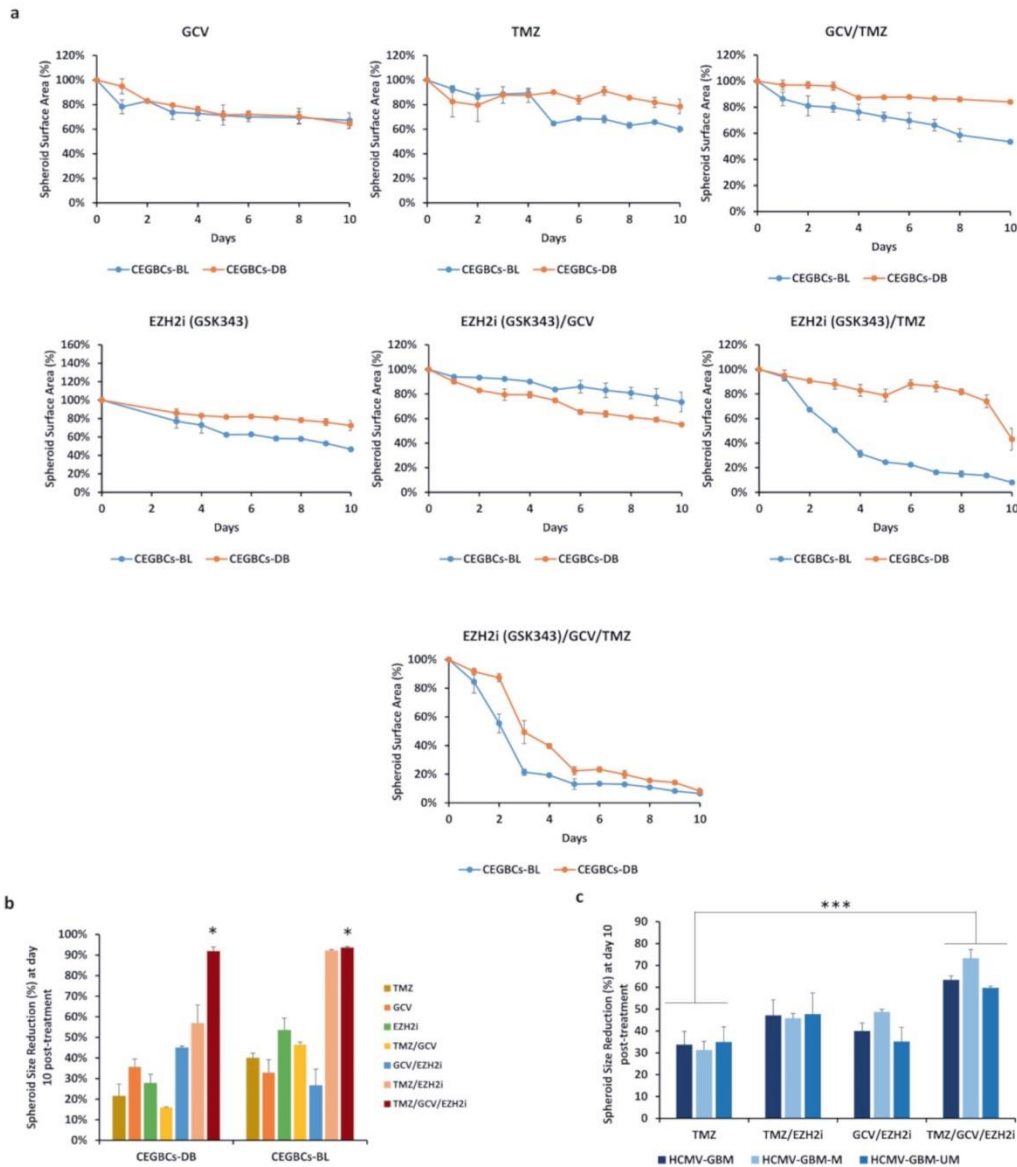

## DISCUSSION

In the present study, we assessed the potential transforming capacities of HCMV-DB and BL following the HAs infection, previously classified into high-risk transforming strains [15, 24, 37, 38]. HAs infection with the high-risk HCMV-DB and BL strains resulted in a pro-oncogenic cellular environment and sustained growth of CEGBCs with soft agar colonies formation, unlike HAs infected with the low-risk HCMV-KM and FS strains that showed no transforming potentials and resulted in cell death in the long term cultures. CEGBCs displayed a "go and growth" phenotype in 2D monolayer cultures, dedifferentiated and displayed stemness as well as PMT features, and finally resulted in spheroid formation and invasion in 3D cultures (Supplementary Fig. 14). PGCCs appearance as well as cellular heterogeneity were previously allied to cultures of mammary epithelial cells infected with the high-risk HCMV strains [15, 39]. Similar to HMECs transformed with the high-risk HCMV strains, around day 80 post-infection, we observed the appearance of dense cell aggregates, followed by the emergence of a wide array of morphologically distinct cells in HCMV-DB and BL cultures (Fig. 2a and Supplementary Fig. 4). We named these cells CMV-elicited glioblastoma cells (CEGBCs) with reference to the CMV-transformed HMECs (CTH) cells. PGCCs, NPC-like, neuron-like and

mesenchymal-like cells were detected as well as filopodia, lamellipodia, and asymmetric cell division patterns (Fig. 3, Supplementary Fig. 10, and Supplementary Fig. 15). The described patterns could be representative of self-renewing cells undergoing diverse stages of the previously described giant cell cycle [15, 39], although blastomere-like structures weren't so far detected as reported previously in CTH cells [15]. A replication-competent virus susceptible to reactivation from latency upon TPA treatment has been detected in CEGBC cultures. Activation of the Myc/EZH2 axis was observed in acute and sustained chronic infection with both high-risk HCMV strains. In agreement with EZH2 activation by HCMV, we observed a direct interaction between EZH2 and HCMV lncRNA4.9 transcript, likewise between EZH2 and cellular lncRNA HOTAIR transcript, a poor prognosis oncogenic factor for glioma patients. In line with EZH2 and HCMV involvement in our glioblastoma model, combination triple therapy (GSK343/GCV/TMZ) curtailed the growth of CEGBCs-derived spheroids. In vivo, all GBM tumor biopsies were found to harbor HCMV with enhanced EZH2 and Myc expression, possessing a strong positive correlation between EZH2 and Myc expression as well as a strong correlation between EZH2/Myc and HCMV presence. Eleven HCMV-GBM strains were isolated from GBM tumors which acutely transformed HAs toward CEGBCs with increased EZH2/Myc expression that undergo dedifferentiation towards glioblastoma stem cells with spheroid formation and invasiveness capacities that could be curtailed by GSK343/GCV/TMZ triple therapy.

Among the mechanisms studied to transform HAs and promote disease progression in addition to poor prognosis in GBM, is the coupling of Myc and EZH2 overexpression as well as the depletion of retinoblastoma protein (Rb) (Fig. 1 and Supplementary Fig. 3) which was observed in our study [17, 40]. Although limited Myc upregulation and Rb downregulation were observed, none of the two low-risk HCMV-KM and FS strains transformed HAs as measured by soft agar colony formation in addition to the cell death observed in prolonged cultures (Supplementary Fig. 1). On the other hand, the high-risk clinical isolates HCMV-DB and BL can drive HAs towards oncogenic transformation in vitro. Our findings conform to the "astrocyte dedifferentiation theory" corresponding to glioblastoma origin [41–43]. In contrast to uninfected HAs, the distinct transcriptome profile including oncogenes, tumor suppressor genes and cell cycle genes facilitated the characterization of CEGBCs that possess a glioblastoma-like phenotype [44, 45]. Stemness acquisition, commonly described in metastasis and poorly differentiated tumors [46–48], is in accordance with previous findings where GB-generated spheroids are composed of glioma stem cells (GSCs). The concomitant presence of the stemness marker nestin and HCMV-IE1 was detected in the spheroid structures generated from CEGBCs, as reported for nestin in the cell lines derived from GBM [49]. Highly motile Nestin/IE1-

**Fig. 8** The effect of diverse single and combination therapies on CEGBCs' growth. **a** Curves representing the spheroid surface area corresponding to CEGBCs-DB and BL under GCV(20  $\mu$ M), TMZ(50  $\mu$ M), GCV(20  $\mu$ M)/TMZ(50  $\mu$ M), GSK343 (0.1  $\mu$ M), GSK343 (0.1  $\mu$ M)/ GCV(20  $\mu$ M), GSK343 (0.1  $\mu$ M)/TMZ(50  $\mu$ M), and GSK343 (0.1  $\mu$ M)/GCV(20  $\mu$ M)/TMZ(50  $\mu$ M) therapies. **b** Histogram representing the CEGBCs-DB and BL spheroids size reduction 10 days post-treatment. positive cells were spotted leaving the core which are similar to the neural-progenitor-like tumor cells detected in glioblastoma, especially the ones adopting the Lévy-like movement patterns [1, 33]. The concomitant presence of viral proteins and nestin

within transformed cells has been reported for the two herpes oncoviruses EBV and KSHV [50, 51]. In agreement with enhanced CD44 and CD133 expression in CEGBCs, their expression in glioblastoma stem cells correlates with cell proliferation, intra-

tumor heterogeneity, invasion and poor prognosis in CD44-expressing glioma [46, 52]. The presence of vimentin<sup>+</sup>/CD44<sup>+</sup> cells in CEGBC cultures as well as the detection of stem cells expressing SOX2 and nestin confirms the PMT plasticity. In agreement with the proneural-mesenchymal plasticity described upon oncogenic stress activation highlighting astrocyte plasticity/reactivity during tumorigenesis [32, 53, 54], a high invasive potential was observed in CEGBCs-DB compared to BL with increased mesenchymal traits indicating a more aggressive behavior that might drive therapeutic resistance.

Accumulated evidence highlighted Myc and EZH2 as key players in both oncogenesis and stemness. Myc stimulates EZH2 expression by activating the EZH2 promoter [55], repressing miR-26a [20], or directly suppressing miR-137. Bromodomain-4 protein (BRD4) positively regulates EZH2 transcription through Myc upregulation [56]. Myc activation was reported in glioblastoma progression, particularly in poor prognosis and therapy resistant-tumors [55, 57]. EZH2 mediates proliferation, migration, and invasion in GBM. High-risk HCMV clinical strains DB and BL differentially induce Myc upregulation, and consequently stimulate EZH2 overexpression as well as CEGBCs induction, pointing toward the presence of Myc/EZH2/CEGBCs axis underlying the described results. Though, the interrelationship between HCMV and EZH2 is further complexed by the detection of HCMV lncRNA4.9 gene in CEGBCs which is in line with Rossetto et al. report [21]. Consistent with our data, the cellular lncRNA HOTAIR was described to interact with EZH2 in glioblastoma, thus linked to tumor dissemination, PMT, and drug resistance [57, 58]. The noticeable detection of high lncRNA HOTAIR in the EZH2 IP samples corresponding to CEGBCs-DB explicates the aggressiveness of this particular high-risk HCMV strain, predicting poor prognosis. Indeed, EZH2-mediated stemness could underlie the appearance and maintenance of CEGBCs expressing a high degree of embryonic stemness, as EZH2 expression in astrocytes induced their dedifferentiation toward stem-like cells expressing nestin, SOX2, and CD133 [43]. Further, we reported the detection of HCMV in GBM tumor biopsies displaying enhanced EZH2, Myc, and Akt expression (Fig. 5 and Supplementary Fig. 11). HCMV-induced Myc and EZH2 expression along with the embryonic stem-like phenotype in the IE1-expressing CEGBCs could establish a significant model in the context of GBM.

Since EZH2 and Myc have been implicated in tumor initiation and proven to impact glioblastoma appearance and development with the two high-risk HCMV DB and BL strains isolated from biological fluids (cervical swab and urine respectively), we evaluated EZH2/Myc expression and recovered HCMV strains directly from GBM biopsies thereby assessing their oncogenic potential. Eleven HCMV strains were isolated from GBM tumors (with unmethylated and methylated MGMT promoters). After HAs infection, CEGBCs were generated with morphological features matching the previously described CEGBCs-DB and BL and led to the appearance of spheroids with invasiveness potential. HCMV-IE1 protein detection parallel to stemness markers and the upregulated Myc and EZH2 expression parallel to the detection of lncRNA4.9 gene, lncRNA4.9 and HOTAIR transcripts in cultures infected with the eleven HCMV-GBM strains recapitulates the previously observed molecular phenotype induced by HCMV-DB and BL strains. The expression of Myc was predominantly elevated in IE1-positive HAs (Supplementary Fig. 12). Altogether, HCMV strains are present in GBM tumors retaining tumor-promoting abilities, therefore considered as oncogenic strains.

Highlighting the critical role of EZH2 and HCMV in our glioblastoma model, the impact of EZH2 inhibitor (GSK343) and anti-HCMV drug ganciclovir (GCV) alone and in combination with TMZ was assessed. TMZ possessed a very limited effect on the growth of CEGBCs spheroids derived from HCMV-DB, HCMV-BL and the eleven HCMV-GBM strains. In agreement with our

results, valganciclovir possessed a positive effect on glioblastoma tumors with an unmethylated or methylated MGMT promoter gene [28], potentially through its antiproliferative effect [59, 60]. Although GSK343 single therapy had a limited effect on the growth of CEGBCs spheroids, its combination with TMZ enhanced the restriction of the CEGBCs spheroids growth derived from DB and BL, and to a lesser extent HCMV-GBM strains. EZH2 may modulate TMZ resistance where blocking EZH2 reverses TMZ chemosensitivity in GBM patients; an increased number of apoptotic cells were detected by knocking down EZH2 [61]. Although encouraging responses were detected post-dual therapy (GSK343/TMZ) in CEGBCs-DB and BL, and to a lesser extent from the eleven GBM HCMV strains, the triple therapy (TMZ/GSK343/GCV) was the most effective in CEGBCs derived from DB, BL, and the eleven GBM HCMV strains. Hence, triple therapy provides the foundation for a combinational therapeutic strategy to improve overall patient survival, reduce viral resistance, and lower drug toxicity.

In conclusion, our data indicated that high-risk HCMV strains and more importantly all the HCMV-GBM strains isolated directly from GBM biopsies can induce a CEGBCs phenotype with tumor heterogeneity, proneural to mesenchymal plasticity, and embryonic-like stemness leading to spheroid formation and invasiveness. Our findings highlight the presence of a potential link between HCMV infection, Myc/EZH2 upregulation and CEGBCs induction in vitro and in GBM biopsies. A more detailed analysis of target genes within CEGBCs and their corresponding response to inhibitors may establish new avenues to understand the complex pathogenesis of glioblastoma and open the door for targeted therapies.

## MATERIALS AND METHODS

### Cell cultures

Primary human astrocytes (HAs) and human embryonic lung fibroblasts (MRC5) were cultured as described in "Supplementary Materials and Methods".

### Viruses

Clinical HCMV strains, namely HCMV-DB (GenBank KT959235), BL (GenBank MW980585), KM, and FS were isolated from patients that were hospitalized at Besançon University Hospital (France) as described previously [7, 15]. Cell-free virus stocks and infections were performed as previously detailed [15]. Careful screening of our viral stocks was conducted to rule out the presence of other oncoviruses [15]. Infections of HAs and MRC5 cells, quantification of viral replication, and HCMV detection were performed as described previously [15] and in "Supplementary Materials and Methods". Primers used are listed in Supplementary Table 1.

### Isolation and growth of CEGBCs

Upon the appearance of large cellular clusters/structures in HAs cultures that were infected with HCMV-DB and BL isolates, clusters were gently detached, cultured in astrocytes medium (Innoprot), and maintained in culture for more than 10 months. CEGBCs were cultured as described in "Supplementary Materials and Methods".

### Western blotting

Expression of IE1, pp65, Myc, EZH2, Akt, and pAkt in uninfected HCMV-infected HAs was assessed as described previously [7].  $\beta$ -actin was used as loading control. Antibodies used are supplied in Supplementary Table 2.

### Flow cytometry analysis

Cells ( $1 \times 10^5$ ) were collected from uninfected HAs, HCMV-infected HAs, and CEGBCs, fixed, permeabilized, and stained as previously reported [15]. The antibodies used are provided in Supplementary Table 2.

### RT<sup>2</sup> profiler PCR array

The RT<sup>2</sup> profiler PCR array was performed as detailed previously [62] and in "Supplementary Materials and Methods".

**RNA cross-linking immunoprecipitation (RNA CLIP) assay**

RNA CLIP assay was performed on CEGBCs and uninfected HAs as previously reported [21, 24]. qPCR analysis of EZH2 immunoprecipitated samples (IP EZH2) and negative control (IP IgG) were normalized with respect to each input and expressed as  $(2^{-\Delta\Delta Ct}) \times 100$  (% Input) as previously reported [63]. The antibodies used are provided in Supplementary Table 2.

**Reverse transcription quantitative polymerase chain reaction (RT-qPCR)**

The detection of transcripts was assessed by RT-qPCR as detailed previously [62] and in "Supplementary Materials and Methods". Primers used are listed in Supplementary Table 1.

**Confocal microscopy**

Confocal microscopy of infected human astrocytes, MRC5 cells, CEGBCs, and spheroids was performed as previously detailed [15]. The antibodies used are provided in Supplementary Table 2.

**Soft agar colony formation assay**

Colony formation in soft agar (Colorimetric assay, CB135; Cell Biolabs Inc., San Diego, CA) seeded with uninfected HAs or CEGBCs was performed as described previously [15].

**Spheroid formation assay**

Spheroids of CEGBCs were prepared as described previously [64, 65]. Detailed description is provided in "Supplementary Materials and Methods".

**Invasion assays**

Detailed description of the invasion assays is provided in "Supplementary Materials and Methods".

**Glioblastoma multiforme biopsies and HCMV isolation**

GBM biopsies ( $n = 37$ ; O (6)-methylguanine DNA methyltransferase (MGMT) promoter methylated GBM biopsies  $n = 17$ , and MGMT promoter unmethylated GBM biopsies  $n = 20$ ) as well as healthy brain biopsies ( $n = 4$ ) were provided by the Regional tumor bank (BB0033-00024 Tumorothèque Régionale de Franche-Comté). A written informed consent for participation was obtained from all patients. The study was authorized by the local ethics committees of Besançon University Hospital (Besançon, France) and the French Research Ministry (AC-2015-2496, CNIL n°1173545, NF-S-138 96900 n°F2015). Detailed description of biopsies analysis is provided in "Supplementary Materials and Methods". Briefly, genomic DNA was isolated from patient biopsies, and HCMV presence was identified by qPCR using specific primers against IE1 and UL69 genes. RNA was extracted from the biopsies, and following reverse transcription the expression of EZH2, Myc, and GAPDH was assessed by real-time qPCR. Eleven HCMV-GBM strains were isolated from MGMT promoter methylated ( $n = 4$ ) and promoter unmethylated ( $n = 7$ ) GBM biopsies. Primers used are listed in Supplementary Table 1.

**Statistical analysis**

Detailed description of the statistical tests used is provided in "Supplementary Materials and Methods".

**DATA AVAILABILITY**

The data supporting the findings of this study are available within the article and its Supplementary Information files and from the corresponding authors on request.

Haidar Ahmad S, **El Baba R**, Herbein G. Polyploid giant cancer cells, cytokines and cytomegalovirus in breast cancer progression. *Cancer Cell Int* 2023;23:119. <https://doi.org/10.1186/s12935-023-02971-1>.

This study investigates the connection between human cytomegalovirus (HCMV) and breast cancer, focusing on high-risk HCMV strains. It finds that high-risk HCMV strains contribute to oncogenic effects leading to aggressive breast cancer. We examined cytokine expression in HCMV-transformed cells and breast cancer biopsies, revealing a correlation between cytokine production and the presence of polyploid giant cancer cells (PGCCs) in both in vitro and in vivo settings. This suggests the potential for novel therapies, particularly cytokine-based immunotherapy, in treating aggressive basal-like breast cancer associated with high-risk HCMV strains.

# Polyploid giant cancer cells, cytokines and cytomegalovirus in breast cancer progression

Sandy Haidar Ahmad<sup>1</sup>, Ranim El Baba<sup>1</sup> and Georges Herbein<sup>1,2\*</sup>

## Abstract

**Background** Breast cancer is the most common cancer among women. Accumulated evidence over the past decades indicates a very high prevalence of human cytomegalovirus (HCMV) in breast cancer. High-risk HCMV strains possess a direct oncogenic effect displayed by cellular stress, polyploid giant cancer cells (PGCCs) generation, stemness, and epithelial-to-mesenchymal transition (EMT) leading to cancer of aggressive phenotype. Breast cancer development and progression have been regulated by several cytokines where the latter can promote cancer cell survival, help in tumor immune evasion, and initiate the EMT process, thereby resulting in invasion, angiogenesis, and breast cancer metastasis. In the present study, we screened cytokines expression in cytomegalovirus-transformed HMECs (CTH cells) cultures infected with HCMV high-risk strains namely, HCMV-DB and BL, as well as breast cancer biopsies, and analyzed the association between cytokines production, PGCCs count, and HCMV presence in vitro and in vivo.

**Methods** In CTH cultures and breast cancer biopsies, HCMV load was quantified by real-time qPCR. PGCCs count in CTH cultures and breast cancer biopsies was identified based on cell morphology and hematoxylin and eosin staining, respectively. CTH supernatants were evaluated for the production of TGF- $\beta$ , IL-6, IL1- $\beta$ , and IL-10 by ELISA assays. The above-mentioned cytokines expression was assessed in breast cancer biopsies using reverse transcription-qPCR. The correlation analyses were performed using Pearson correlation test.

**Results** The revealed PGCCs/cytokine profile in our in vitro CTH model matched that of the breast cancer biopsies, in vivo. Pronounced cytokine expression and PGCCs count were detected in particularly CTH-DB cultures and basal-like breast cancer biopsies.

**Conclusions** The analysis of cytokine profiles in PGCCs present mostly in basal-like breast cancer biopsies and derived from CTH cells chronically infected with the high-risk HCMV strains might have the potential to provide novel therapies such as cytokine-based immunotherapy which is a promising field in cancer treatments.

**Keywords** Human cytomegalovirus, High-risk HCMV strains, CTH cells, PGCCs, Cytokines, Breast cancer biopsies

## Introduction

Polyploid giant cancer cells (PGCCs) play an important role in tumor heterogeneity; they are implicated in tumor initiation, progression, metastasis, and therapy resistance in breast, ovarian, and prostate cancers [1, 2]. PGCCs count was associated with tumor grade and metastasis degree in patients with breast cancer (BC) [3]. PGCCs promote BC metastasis and

chemoresistance by modulating the tumor microenvironment (TME) [1, 4]. The presence of polyploidy was identified as a common characteristic among all the tumors initiated by oncoviruses [5]. Human cytomegalovirus (HCMV), a ubiquitous beta-herpesvirus, exhibits a broad cellular tropism [6]. HCMV genome and/or antigens were detected in numerous malignancies including breast, ovarian, prostate, and colon cancer, as well as in neural-derived cancers such as glioblastoma, neuroblastoma, and medulloblastoma. The potential relation between HCMV and cancer was explained by the oncomodulation paradigm [7–12]. Besides the oncomodulation paradigm, our research group highlighted a direct oncogenic effect of high-risk HCMV strains [13–17]. Following human mammary epithelial cells (HMECs) infection, high-risk strains namely, HCMV-DB and HCMV-BL transformed HMECs into cytomegalovirus-transformed HMECs (CTH cells) [16, 17]. PGCCs appearance was described in CTH cultures and associated with enhanced cell proliferation, activation of epithelial-to-mesenchymal transition (EMT), and stemness processes [17, 18]. Moreover, the expression of HCMV-IE1 was identified in PGCCs-CTH cells [17, 18]. These studies highlighted the emergence of PGCCs as a critical factor following HCMV infection.

Numerous studies have described the capacity of cytokines to regulate the induction and progression of breast cancer. Several interleukins including IL-1, IL-6, IL-11, IL-19, and transforming-growth factor  $\beta$  (TGF- $\beta$ ) promoted breast cancer cell proliferation and/or invasion [19, 20]. TGF- $\beta$ , the most studied cytokine in breast cancer, plays a dual role in tumor progression. At an early stage of tumorigenesis, TGF- $\beta$  acts as a tumor suppressor due to its anti-proliferative effects. At late stages, TGF- $\beta$  induces tumor progression by enhancing cancer cell invasion, survival, and immune evasion [21–24]. Furthermore, the presence of TGF- $\beta$  in the microenvironment correlates with tumor progression and poor prognosis [22]. IL-6 is capable to convert non-stem cancer cells to cancer stem-like cells in breast and prostate cell lines [25]. IL-1 and IL-10 are highly expressed in high grade breast cancer [26–28]. Further, the IL-1 was associated with cancer cells' proliferation, invasion, angiogenesis, and breast cancer metastasis [29, 30]. IL-6, and IL-1 activate NF- $\kappa$ B and increase cyclin D1 in the normal breast cells causing a neoplastic phenotype [31]. Furthermore,

IL-6 and TGF- $\beta$  initiate the epithelial-to-mesenchymal transition (EMT) process [24, 32–35] leading to cancer progression and metastasis [34, 36, 37]. Additionally, some cytokines including TGF- $\beta$ , IL-10 and IL-6 were described to facilitate tumor escape [38–41]. Herein, we screened cytokines expression in CTH cultures as well as breast cancer biopsies, and analyzed the link between cytokines production, PGCCs, and HCMV presence in vitro and in vivo.

## Materials and methods

### Cells cultures

Human primary mammary cells (HMECs) were purchased from Life Technologies (Carlsbad, CA, USA). HMECs were cultured in HMEC medium supplemented with HMEC supplement, bovine pituitary extract, and penicillin/streptomycin (Life Technologies) at 37 °C, 5% CO<sub>2</sub>, and 95% humidity. HMECs were infected with high-risk strains HCMV-DB (KT959235) and HCMV-BL (MW980585) at MOI of 1 as previously described [17, 42]. Following chronic infection, CMV-Transformed HMECs (CTH) cells were emerging and cultured in the same conditions as HMECs. CTH cells were maintained in culture for more than 12 months. Mycoplasma contamination status was monitored on a monthly basis for all cultures (VenorGem classic mycoplasma detection, Minerva biolabs).

### Breast biopsies

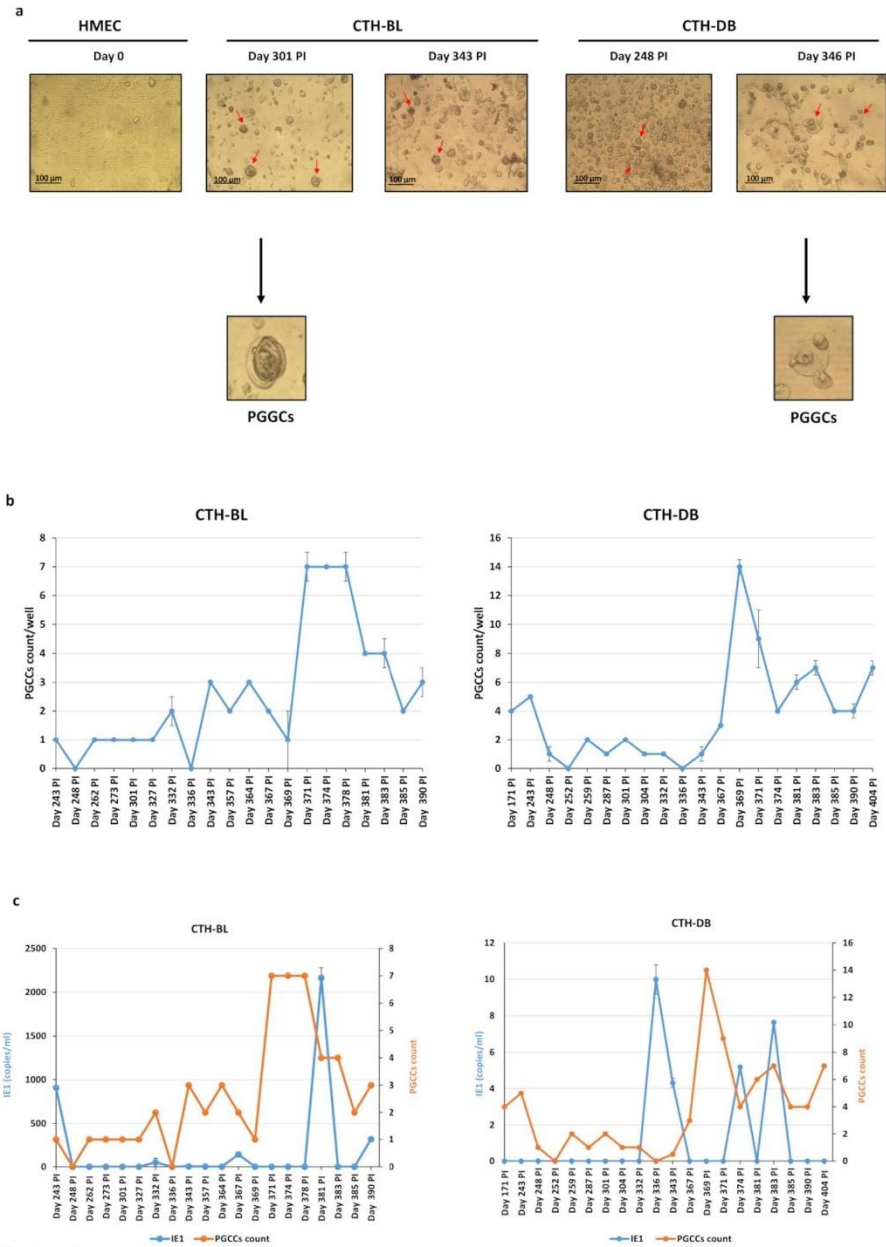

Healthy breast biopsies (n=4) and breast cancer biopsies (n=16: luminal tumor biopsies n=8 and basal tumor biopsies n=8) were provided by the Regional Tumor Bank (BB0033-00024 Tumorothèque Régionale de Franche-Comté). The local ethics committees of Besançon University Hospital (Besançon, France) and the French Research Ministry (AC-2015-2496, CNIL n°1173545, NF-S-96900 n° F2015) permitted the study. All patients provide their written informed consent to participate in the study.

### Viral detection

Real-time qPCR was used to assess the presence of HCMV in CTH cultures and breast cancer biopsies. DNA

Data are represented as mean  $\pm$  SD of two independent experiments. Blue and orange curves represent the viral load (copies/ml) as measured by IE1-qPCR (Left Y-axis) and PGCCs count/well (Right Y-axis), respectively. The X-axis represents the days post-infection

**Fig. 1** (See legend on previous page.)

was extracted from CTH supernatants using E.Z.N.A. Blood DNA Kit, D3392-02, Omega BIO-TEK). Genomic DNA isolated from patient breast tumor biopsies and healthy human breast tissue was provided by the Regional Tumor Bank (BB0033-00024 Tumorotheque Régionale de Franche-Comté). Viral load was quantified by qPCR using KAPA SYBR FAST Master Mix (KAPA BIOSYSTEMS, KK4601) and IE1 primers (Forward 5'-CGACGT TCCTGCAGACTATG-3' and reverse 5'-TCCTCGGTC ACTTGTTCAAA-3') according to the manufacturer's protocol. Reactions were activated at 95 °C for 10 min, followed by 50 cycles (15 s at 95 °C and 1 min at 60 °C). Real-time qPCR reactions were conducted using a Stratagene Mx3005P thermocycler (Agilent). Results were analyzed using MxPro qPCR software.

#### PGCCs detection and count in CTH cultures and biopsies

CTH cells were monitored by an Olympus optical microscope (Japan) and OPTIKA microscopy digital camera (Opticam, Italy). PGCCs present in CTH cultures were identified and counted based on cell morphology as previously reported [18]. PGCCs presence in BC biopsies was confirmed by hematoxylin and eosin staining based on Zhang et al. PGCCs description [43]. PGCCs quantification was similarly performed for all breast cancer biopsies. Briefly, PGCCs were counted in five hot spots of each tumor sample in hematoxylin and eosin slides (magnification 400X, field diameter 0.45 mm).

#### Cytokines production and expression in CTH cultures and biopsies

Supernatants from CTH cultures were harvested on different days post-infection and evaluated for the presence of cytokines. ELISA kits were used for the detection of Human TGF- $\beta$  (kit reference 650.010.096, Diaclone, France), human IL-6 (kit reference 851.520.001, Diaclone, France), human IL-1 $\beta$  (kit reference 851.610.001, Diaclone, France), and human IL-10 (kit reference 851.540.005, Diaclone, France) in CTH supernatants. ELISA assays were performed according to the manufacturer's protocol.

Cytokines expression in breast cancer biopsies was evaluated by reverse transcription-quantitative polymerase chain reaction (RT-qPCR). Total RNA was extracted from BC biopsies using E.Z.N.A. Total RNA Kit I (Omega Bio-Tech, GA, USA). Following DNase I treatment

(ThermoFisher), reverse transcription was performed using the SuperScript IV First-Strand Synthesis kit (Invitrogen, Carlsbad, CA, USA). Expression of TGF- $\beta$ , IL-6, IL-1 $\beta$ , and IL-10 was measured by real-time qPCR using KAPA SYBR FAST Master Mix (KAPA BIOSYSTEMS, KK4601) and specific primers (listed in Additional file 1: Table S1) according to the manufacturer's protocol. The cytokines analyzed in the tissue samples were normalized to the housekeeping gene GAPDH. The GAPDH primers used are listed in Additional file 1: Table S1.

#### Statistics

The statistic software SPSS 23 was used to analyze the data. Correlation analyses were performed using Pearson correlation test.  $p$ -value  $\leq 0.05$  was considered significant. Plots and histograms were executed using Microsoft Excel. Data are presented as mean  $\pm$  SD of two independent experiments.

#### Results

##### Kinetics of PGCCs appearance in CTH cultures

CTH cells were maintained in culture for more than 12 months as previously reported [17, 18]. After chronic infection, CTH cells exhibit an extremely heterogeneous population. Compared to uninfected HMECs, we identified the presence of large cells with morphological heterogeneity in chronic CMV-transformed-HMECs (CTH)-BL and CTH-DB (Fig. 1a, red arrows). Besides the presence of small-sized cells, giant cells with large nuclei, as well as giant cells with blastomere-like morphology and mesenchymal cells, were identified in CTH cultures parallel to the asymmetric cell division patterns; these giant cells were named PGCCs as previously reported [17, 18]. The PGCCs count was monitored from day 171 to 404 and from day 243 to 390 in chronically infected CTH-DB and CTH-BL cultures, respectively. The PGCCs count in CTH-BL cultures increased slightly at day 343 post-infection and reached a peak at days 371, 374, and 378 post-infection. A higher PGCCs count was observed in CTH-DB cultures, especially at day 369 post-infection (Fig. 1b). Furthermore, we assessed the presence of HCMV in CTH cultures using real-time qPCR. HCMV viral load was higher in CTH-BL compared to CTH-DB cultures. Viral replication was noticed in the presence of low PGCCs count in CTH cultures (Fig. 1c).

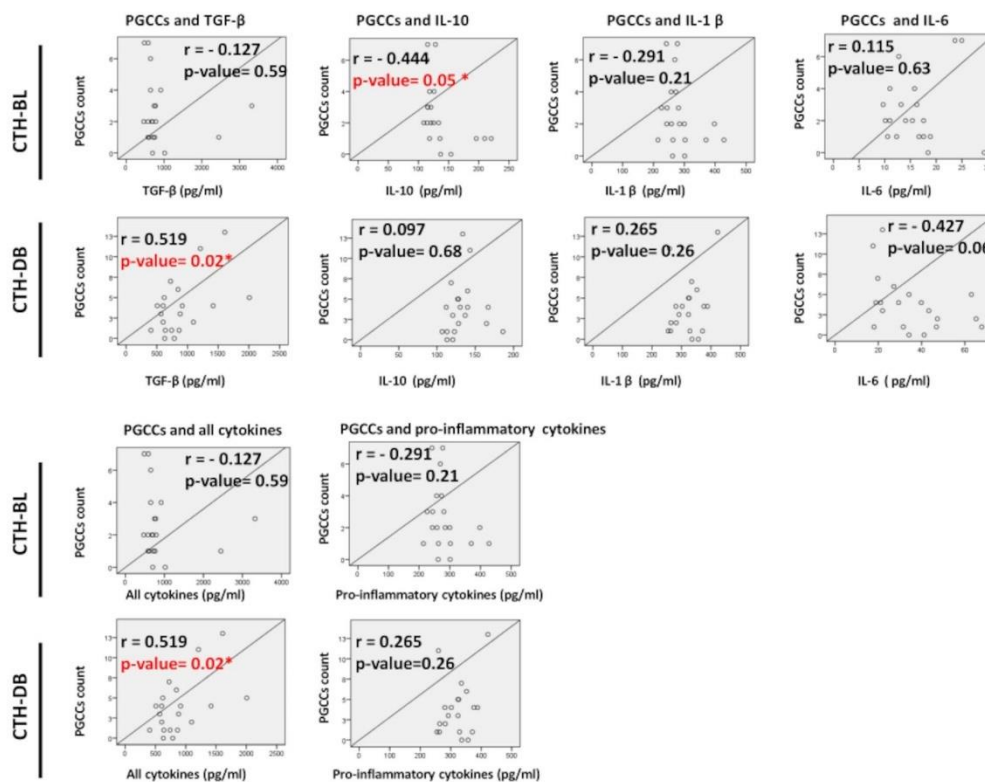

(See figure on next page.)

**Fig. 2** Cytokines production in CTH cultures. Cytokines TGF- $\beta$  (a), IL-10 (b), IL-1 $\beta$  (c), and IL-6 (d) were measured in supernatants of CTH cultures by ELISA kits. Remarkably, TGF- $\beta$  concentration was enhanced along with the PGCCs count in the CTH-DB culture. IL-10 concentration was reduced in the CTH-BL culture with the presence of a high PGCCs count. The higher IL-6 expression was detected in CTH-DB culture. Data are represented as mean  $\pm$  SD of two independent experiments. Blue and orange curves represent the cytokine concentration (pg/ml) (Left Y-axis) and PGCCs count/well (Right Y-axis), respectively. The X-axis represents the days post-infection

**Fig. 2** (See legend on previous page.)

**Fig. 3** Correlation between PGCCs count and cytokines production in CTH cultures. Pearson's correlation between PGCCs count and cytokine production was conducted in CTH cultures. A statistically significant negative correlation was detected between IL-10 expression and PGCCs count in CTH-BL culture. Moreover, a significant strong positive correlation was observed between PGCCs count and TGF-β or all cytokines production in CTH-DB cultures. The X-axis represents cytokine concentration (pg/ml), and the Y-axis represents PGCCs count. All cytokines: TGF-β, IL-6, IL-10, IL-1β, Pro-inflammatory cytokines: IL-1β and IL-6. (r) stands for correlation coefficient and (\*) shows significant p-value  $\leq 0.05$

#### Kinetics of cytokines production (TGF-β, IL-1β, IL-6, and IL-10) in CTH cultures

We assessed cytokines production in CTH cultures using ELISA assays (Fig. 2). The cytokine TGF-β was detected in CTH-BL and DB cultures at a concentration ranging between 500 and 3400 pg/ml. The highest TGF-β concentration was noticed at day 343 post-infection in CTH-BL culture. Remarkably, the TGF-β concentration was increased along with the PGCCs count in the CTH-DB culture (Fig. 2a). The production of IL-10 and IL-1β slightly varied between CTH-BL and CTH-DB cultures (Fig. 2b and c). Particularly, IL-10 concentration was decreased in the CTH-BL culture with the presence of a high PGCCs count (Fig. 2b). Higher expression of IL-6 was induced in CTH-DB compared to CTH-BL (Fig. 2d).

#### Correlation between PGCCs/cytokine production depends on the HCMV strain (DB versus BL)

We analyzed the link between viral load or PGCCs presence and cytokines production using Pearson's correlation test. We noticed a statistically significant negative correlation between IL-10 expression and PGCCs count in CTH-BL ( $r = -0.444$ ,  $p\text{-value} = 0.05$ ) (Fig. 3 and Table 1). Furthermore, TGF-β or all cytokines production were strongly and positively correlated with PGCCs count in CTH-DB culture ( $r = 0.519$ ,  $p\text{-value} = 0.02$ , and  $r = 0.519$ ,  $p\text{-value} = 0.02$ , respectively) (Fig. 3). No other statistically significant correlation was detected between the remaining cytokines and PGCCs count (Table 1). For example, a non-significant negative correlation was detected

**Table 1** Correlation between PGCCs count and cytokines production in CTH cultures

	Correlation between PGCCs and the cytokines below	r	p-value
CTH-BL	TGF- $\beta$	-0.127	0.59
CTH-DB		0.519	0.02*
CTH-BL	IL-10	-0.444	0.05*
CTH-DB		0.097	0.68
CTH-BL	IL-1 $\beta$	-0.291	0.21
CTH-DB		0.265	0.26
CTH-BL	IL-6	0.115	0.63
CTH-DB		-0.427	0.06
CTH-BL	All cytokines	-0.127	0.59
CTH-DB		0.519	0.02*
CTH-BL	Pro-inflammatory cytokines	-0.291	0.21
CTH-DB		0.265	0.26

All cytokines: TGF- $\beta$ , IL-6, IL-10, IL-1 $\beta$ . Pro-inflammatory cytokines: IL-1 $\beta$  and IL-6. (r) stands for correlation coefficient and (\*) shows significant p-value  $\leq 0.05$ . between PGCCs count and IL-6 production in CTH-DB culture ( $r = -0.427$ ,  $p\text{-value} = 0.06$ ) (Fig. 3). No significant correlation was found between HCMV presence (IE1 gene) and cytokines production (Fig. 4).

#### Detection of PGCCs and cytokines, as well as the correlation between PGCCs/cytokine expression in BC biopsies

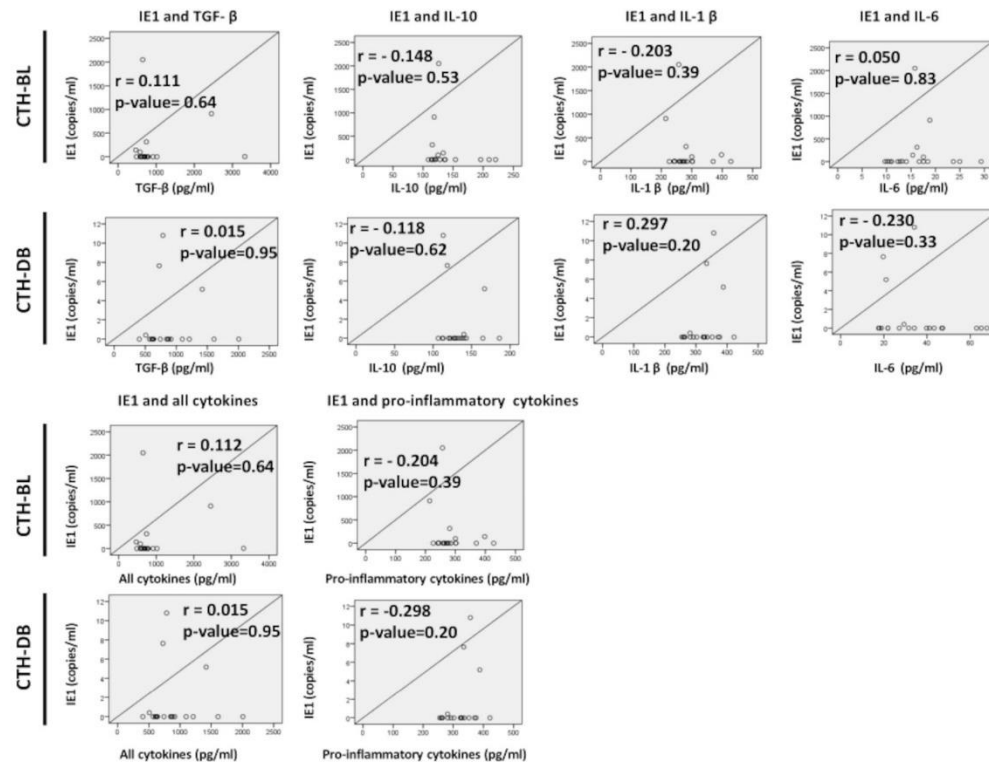

To further decipher the relation between PGCCs count and cytokine production in vivo, we analyzed sixteen breast cancer biopsies (luminal  $n = 8$  and basal-like  $n = 8$ ) parallel to four healthy mammary biopsies for the presence of PGCCs, HCMV, as well as cytokine expression. The pathological data for the sixteen breast cancer biopsies were provided in Table 2. PGCCs with giant or multiple nuclei were detected in human breast cancer biopsies, in particular basal-like breast cancer biopsies (Fig. 5, arrows). Compared to healthy biopsies, high expression of TGF- $\beta$ , IL-1 $\beta$ , and IL-10 was reported in BC biopsies, notably in basal-like biopsies; a slight variation in IL-6 expression was noticed in BC biopsies (Fig. 6). Hence, all cytokines as well as pro-inflammatory cytokines were highly expressed in basal-like BC biopsies compared to healthy biopsies (Fig. 6). As we previously confirmed the positive correlation between PGCCs count and HCMV presence in basal-like breast cancer, we assessed the expression of cytokines in these PGCCs-positive basal-like biopsies. A statistically significant strong positive correlation was identified between HCMV presence and IL-10,

IL-6, all cytokines, and pro-inflammatory cytokines in PGCCs-positive basal-like biopsies ( $r = 0.899$ ,  $p\text{-value} = 0.04$ , and  $r = 0.924$ ,  $p\text{-value} = 0.03$ ,  $r = 0.961$ ,  $p\text{-value} = 0.009$ , and  $r = 0.882$ ,  $p\text{-value} = 0.05$ , respectively) (Fig. 7).

#### Discussion

Polyplloid giant cancer cells (PGCCs) were previously found in vitro and in vivo, and are especially noticeable in poorly differentiated, late-stage, and treatment-resistant cancers [44–46]. PGCCs count is increased in high breast tumor grade and lymph node metastases which suggests a relation between PGCCs and tumor recurrence potential [3]. Moreover, PGCCs were found in MDA-MB-231 and MCF7 breast cancer cell lines [43, 47, 48]. PGCCs induced a mesenchymal phenotype and displayed stem-like properties [3, 43, 46]. In line with these studies, PGCCs were mainly detected in basal-like compared to luminal biopsies. Further, our CTH cells that exhibit PGCCs following chronic HCMV infection were described to display mesenchymal and embryonic-like stemness features [17, 18]. As oncoviruses might trigger PGCCs formation [5], it is worth mentioning the absence of any other oncovirus in our viral stocks and CTH culture, thus confirming that the detected PGCCs phenotype is due to HCMV.

Furthermore, cytokines were described to regulate the induction and protection in breast cancer [31]; overexpression of several cytokines was described in estrogen receptor-negative breast carcinoma [26]. We mainly detected high expression of TGF- $\beta$ , IL-1 $\beta$ , and IL-10 in basal-like breast cancer compared to healthy and luminal biopsies. In agreement with our data, TGF- $\beta$  and IL-6 were described to promote epithelial to mesenchymal transition by downregulating the expression of cell adhesion genes and upregulating the cell motility genes and genes associated with the mesenchymal phenotype [24, 32–34, 49]. This regulation could lead to a complete mesenchymal process (C-EMT) which was strongly associated with basal-like tumors [50, 51]. Additionally, ER-positive breast tumor cells were described to produce lower levels of IL-6 than ER-negative breast tumor cells [52]. Overexpression of IL-6 exhibits an epithelial-to-mesenchymal transition (EMT) phenotype in MCF7 cells and promotes their invasiveness [53]. In line with this study, higher IL-6 production was detected in CTH-DB cultures that previously exhibited more EMT features compared to CTH-BL cultures [17, 18]. However, the inhibition of IL-6 and IL-8 in TNBC cell lines decreased cell survival as well as colony formation, and prevented tumor growth in vivo [54]. Likewise, the expression of IL-1 $\beta$  was mainly reported in a highly malignant invasive mammary cell line (such as MDA-MB-231) [28, 55,

**Fig. 4** Correlation between HCMV presence and cytokines production in CTH cultures. Pearson's correlation between viral load and cytokine production was conducted in CTH cultures. No significant correlation was identified between IE1 gene expression and cytokines production. The X-axis represents cytokine concentration (pg/ml), and the Y-axis represents viral load as measured by IE1 detection using qPCR (copies/ml). All cytokines: TGF-β, IL-6, IL-10, IL-1β, Pro-inflammatory cytokines: IL-1β and IL-6. (r) stands for correlation coefficient

56]. In agreement with our in vivo outcomes, high levels of IL-1β were linked to breast cancer aggressiveness and poor prognosis [26, 57]. In addition, high expression of IL-10 was reported in breast tumors [26, 58].

Cytokines play a critical role not only in tumor growth and metastases but also in tumor evasion.

For instance, the anti-inflammatory cytokine IL-10 inhibits cytokine production and antigen presentation by T cells and macrophages [38, 39]. TGF-β was described to suppress natural killer cells (NK) and promote regulatory T-cell activity through a neuropilin-1-mediated mechanism [24, 59, 60]. This could explain the high IL-10 and TGF-β expression detected in the poor prognosis basal-like breast cancer biopsies compared to the luminal and healthy breast biopsies. Additionally, HCMV-infected tumor cells produce immunosuppressive cytokines such as IL-10 to escape the immune responses and counteract

the pro-inflammatory cytokines production [8, 61]. This might be in line with the significant strong correlation detected between HCMV replication (IE1 expression) and IL-10 production in PGCCs-positive basal-like biopsies.

The HCMV-encoded IL-10, a homolog of the potent human interleukin 10 (hIL-10), possesses a range of immunomodulatory functions, including suppression of pro-inflammatory cytokine production. [62–64]. During viral latency, the expression of latency-associated cmvIL-10 (LAcvIL-10), another isoform of the virus-encoded IL-10, modulates the microenvironment of infected cells and allows immunity evasion [65]. Furthermore, the immune suppressive cytokine TGF-β was reported to stimulate HCMV replication in fibroblast cultures [66]. HCMV produces TGF-β in different tumor cell types including glioblastoma, leukemia, and osteosarcoma cells

[67, 68]. The HCMV IE2 protein enhances TGF- $\beta$  gene transcription by interacting with the Egr-1 DNA-binding protein [69]. Moreover, a comparative study showed that HCMV-IE proteins activated the TGF- $\beta$  promoter in the absence and presence of HCMV infection [68]. Hence, the production of TGF- $\beta$  by HCMV could influence the

infected cells, neighboring tissues and immune responses to benefit from the stimulating viral replication and avoid immune responses through the negative regulatory effects of TGF- $\beta$  on lymphocytes functions [9, 70, 71]. This could further explain the enhanced expression of TGF- $\beta$  detected in CTH cultures and basal-like biopsies.

Latency was reported to be essential for transformation induced by oncogenic herpesviruses [17, 72]. HCMV persistence was described in tubular epithelial cells [73], neural stem cells [74], and osteogenic sarcoma-derived cells [75]. Furthermore, the detection of some lytic blips suggests that both lytic viral replication and viral latency are essential to promote and maintain CTH transformation as previously reported for the other two oncogenic herpesviruses, namely EBV and Kaposi's sarcoma-associated herpesvirus (KSHV) [76, 77]. In addition, the detection of different PGCCs count and cytokine concentrations in CTH cultures suggests that the diversity of HCMV strains could affect the exhibition of PGCCs and cytokines production. Several studies showed that HCMV disease and pathogenesis could be related to HCMV genome diversity [78, 79]. Increasing evidence suggests an association between HCMV genetic diversity and HCMV pathogenesis that could also modulate onco-modulation/oncogenesis [80, 81].

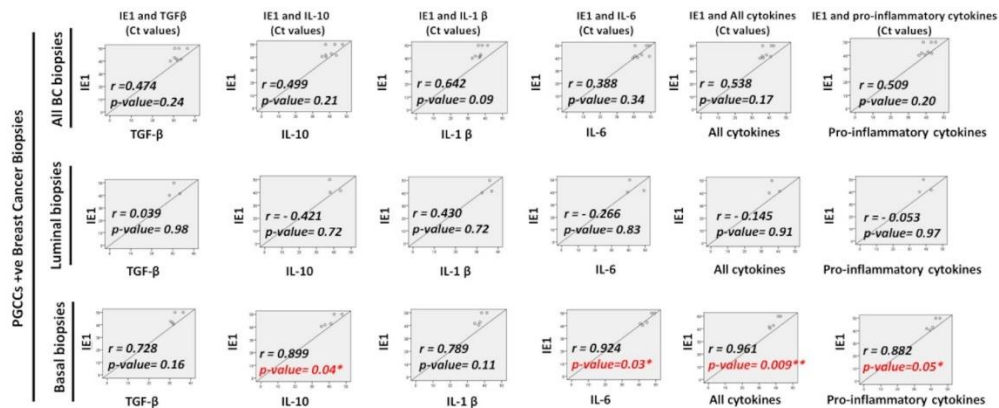

PGCCs detection and cytokines expression depend not only on breast cancer type but also on the tumor microenvironment (TME). The composition of TME is modified by PGCCs through the recruitment of diploid cancer cells from adjacent zones; these diploid cells can

**Fig. 5** PGCCs detection in breast cancer biopsies. Presence of PGCCs in breast cancer biopsies (arrows). The tissue was stained using HES. Magnification: 40X. Scale bars are 50  $\mu$ m

**Fig. 6** Cytokines expression in breast biopsies. Histogram representing the expression of TGF-β, IL-10, IL-6, IL-1β, all cytokines and pro-inflammatory cytokines in healthy breast biopsies, all breast cancer biopsies (BC), as well as luminal and basal biopsies. Cytokines expression in biopsies was assessed by reverse transcription-quantitative polymerase chain reaction (RT-qPCR). Data are represented as mean ± SD of two independent experiments

**Fig. 7** Correlation between HCMV presence and cytokines expression in PGCCs-positive breast biopsies. Pearson's correlation between HCMV load and cytokines expression was conducted in luminal and basal breast cancer biopsies. A statistically significant strong positive correlation was observed between HCMV presence and IL-10, IL-6, all cytokines, and pro-inflammatory cytokines in PGCCs-positive basal-like biopsies. The X-axis represents cytokine expression (Ct value), and the Y-axis represents viral load as measured by IE1 qPCR (Ct value). All cytokines: TGF-β, IL-6, IL10, IL-1β, Pro-inflammatory cytokines: IL-1β and IL-6. (r) stands for correlation coefficient. \*p-value ≤ 0.05; \*\*p-value ≤ 0.01

ultimately become PGCCs [82]. Additionally, PGCCs progeny formation was described to be a part of the TME. PGCCs stemness, metastasis, vasculogenic mimicry and chemoresistance were recognized as the outcomes of the dynamic relationship between PGCCs and the TME [1]. Tumor cells secrete cytokines that recruit and activate other cells in the TME. Moreover, cytokines induce a tumor-supportive immune microenvironment by inhibiting anti-tumor immunity [83]. The inactivation of NF- $\kappa$ B in myeloid cells was described to reduce cytokines expression and tumor size [84]. The inflammatory cytokines including IL-1 $\beta$ , IL-6, IL-8, and CCL-5 that are induced by NF- $\kappa$ B promote tumor growth through the induction of cell proliferation [85]. The tumor-associated macrophage (TAMs), tumor-associated neutrophils (TANs), myeloid-derived suppressor cells (MDSC), and regulatory cells (Tregs) present in the TME are associated with poor prognosis. They produce IL-10 and TGF- $\beta$  that suppress the activity of NK cells, T and B lymphocytes in the TME, allowing the proliferation and survival of cancer cells [85]. Also, TAMs, endothelial cells, and fibroblasts in the TME induce angiogenesis via IL-6, IL-8, and TGF- $\beta$  [86–88]. TAMs promote metastasis and invasion in breast cancer through the secretion of IL-1 $\beta$  [31, 89]. TAMs, the most abundant cells in the TME, were associated with poor prognosis, especially in basal-like breast cancer [90, 91]. Furthermore, the pro-metastatic microenvironmental factor S100A4 was described to stimulate basal-like breast cancer cells to secrete pro-inflammatory cytokines that convert monocytes into TAM-like cells [92]. In line with this data, we detected the highest expression of the pro-inflammatory cytokines, IL-1 $\beta$  and IL-6, in basal-like breast cancer. Moreover, the abundant presence of TAMs in basal-like breast cancer could explain the high expression of TGF- $\beta$  and IL-10 detected in basal biopsies compared to luminal ones. Hence, we highlighted the critical relationship between PGCCs/cytokines present in the TME and the basal-like breast cancer. Furthermore, the significant strong correlation identified between HCMV presence and the expression of IL-10, IL-6, all cytokines and pro-inflammatory cytokines suggested that HCMV presence could regulate cytokines expression in basal-like BC biopsies. High HCMV load might favor EMT features and immune evasion in basal-like BC biopsies by upregulating the expression of cytokines, particularly IL-10 and IL-6. Thus, our outcomes underline the strong link between HCMV load, PGCCs presence and cytokines expression in basal-like breast cancer that displays the most aggressive phenotype.

The *in vitro* PGCCs/cytokine profile present in our CTH model matched the *in vivo* PGCCs/cytokine profile identified in breast cancer biopsies. The highest

IL-6 expression usually linked to EMT and PGCCs count was identified in CTH-DB culture and basal-like biopsies that harbor the most malignant phenotype [17, 18, 93]. Finally, telomere dysfunction-driven polyploidization is a universal source of tumor evolution that occurs continuously during neoplastic cell growth [94]. Oncoviruses deregulate telomerase activity and telomere length and promote cancer development [95]. Interestingly, HCMV activates telomerase [96], and favors the appearance of PGCCs which are considered as hallmarks of oncoviruses [5]. Further studies are needed to investigate the relationship and underlying mechanisms between polyploid cancer cells, cytokines production, and cytomegalovirus.

Our study has some limitations to address. To start with, the limited sample size; higher sample size enhances the significance level of our findings. Furthermore, the restricted cytokine evaluation; assessing more cytokines in CTH cultures and breast cancer biopsies might highlight the potential role of HCMV in cytokine production and cancer progression. Additionally, the absence of characterization of inflammatory cells that might underline the link between HCMV, cytokine production and cancer progression.

## Conclusion

In conclusion, our findings revealed for the first time an association between high-risk HCMV strains, PGCCs formation, and cytokines production *in vitro* and *in vivo*. Our study presents a proof-of-concept for highlighting the cytokine profile in breast cancer, particularly the basal-like breast cancer, parallel to the presence of PGCCs and HCMV detection, thereby opening the door toward new therapeutic approaches in breast cancer patients with poor prognostic characteristics.

## Supplementary Information

The online version contains supplementary material available at <https://doi.org/10.1186/s12935-023-02971-1>.

**Additional file 1: Table S1.** List of primers used.

## Acknowledgements

The authors thank the Pathology Department of Besançon University Hospital for providing the breast cancer biopsies.

## Author contributions

SHA, REB performed experiments. GH, SHA, REB participated to the data analysis. GH conceived and designed the project. SHA, REB, GH wrote the manuscript.

## Funding

This work was supported by grants from the University of Franche-Comté, and the Région Franche-Comté to G.H. S.H.A was supported by ANR (Agence Nationale pour la Recherche) grant. R.E.B. is a recipient of a doctoral scholarship from Apex Biosolutions company. The funders had no role in the data collection, analysis, patient recruitment, or decision to publish.

**Availability of data and materials**

The data supporting the findings of this study are available within the article and its Supplementary Information files and from the corresponding authors on request.

**Declarations****Ethics approval and consent to participate**

The local ethics committees of Besançon University-Hospital (Besançon, France) and the French Research Ministry (AC-2015-2496, CNIL n°1173545, NF-S-96900 n° F2015) permitted the study. All patients provide their written informed consent to participate in the study.

**Consent for publication**

Not applicable.

**El Baba R.** Haidar Ahmad S, Monnien F, Mansar R, Bibeau F, Herbein G. Polyploidy, EZH2 upregulation, and transformation in cytomegalovirus-infected human ovarian epithelial cells. *Oncogene* 2023. <https://doi.org/10.1038/s41388-023-02813-4>.

The present study investigates the connection between human cytomegalovirus (HCMV) infection and epithelial ovarian cancer (OC), particularly high-grade serous ovarian carcinoma (HGSOC). Herein, we identified the presence of polyploid giant cancer cells (PGCCs) with stem cell-like characteristics in HGSOC. Additionally, we highlighted the role of the oncogene EZH2, which correlates with OC tumor grade and proliferation. Our study presents evidence of HCMV's involvement in transforming human ovarian epithelial cells, leading to the creation of "CMV-transformed Ovarian cells" (CTO). High-risk clinical HCMV strains, including the three strains isolated from HGSOC biopsies, induced distinct cellular and molecular changes, including EZH2 upregulation and increased cell proliferation. These findings support the notion of an HCMV-induced model for epithelial ovarian cancer and suggest the tumorigenic properties of EZH2. This research may have implications for targeted therapeutics in the treatment of ovarian tumors.

Human cytomegalovirus (HCMV) infection has been implicated in epithelial ovarian cancer (OC). Polyploidy giant cancer cells (PGCCs) have been observed in high-grade serous ovarian carcinoma (HGSOC); they possess cancer stem cell-like characteristics and give rise to progeny cells expressing epithelial-mesenchymal transition (EMT) markers. EZH2 plays a potential oncogenic role, correlating with high proliferative index and tumor grade in OC. Herein, we present the experimental evidence for HCMV as a reprogramming vector that elicited human ovarian epithelial cells (OECs) transformation leading to the generation of “*CMV-transformed Ovarian cells*” (CTO). The infection with the two high-risk clinical strains, namely HCMV-DB and BL provoked a distinct cellular and molecular mechanisms in infected OECs. EZH2 upregulation and cellular proliferation were curtailed by using EZH2 inhibitors. The HGSOC biopsies were characterized by an elevated EZH2 expression, possessing a strong positive correlation between the aforementioned marker and HCMV. From HGSOC biopsies, we isolated three HCMV clinical strains that transformed OECs generating CTO cells which displayed proliferative potentials in addition to EZH2 upregulation and PGCCs generation; these features were reduced upon EZH2 inhibition. High-risk HCMV strains transformed OECs confirming an HCMV-induced epithelial ovarian cancer model and highlighting EZH2 tumorigenic properties. Our findings might be highly relevant in the pathophysiology of ovarian tumors thereby nominating new targeted therapeutics.

## INTRODUCTION

Epithelial ovarian cancer (OC), the most common and life-threatening cancer amongst gynecologic malignancies, has a 5-year age-standardized survival rate of 30–40%. Nearly 75% of all OC cases are diagnosed at late stages [1]. Despite the advances in treatment modalities, the overall survival remains low for stage III and stage IV accounting for 40 and 20%, respectively. Optimal surgery and platinum-based chemotherapy (such as carboplatin and cisplatin) remain the mainstay of treatment often combined with paclitaxel, gemcitabine, a humanized monoclonal antibody targeting vascular endothelial growth factor (VEGF) bevacizumab, pegylated liposomal doxorubicin, cyclophosphamide, topotecan, poly-ADP-ribose polymerase (PARP) inhibitors, and immune check point inhibitors especially for recurrent OC [2–4]. In some cases, due to the poor blood supply to the peritoneal surface, hyperthermic intraperitoneal chemotherapy (HIPEC) has been used as a therapeutic alternative [5].

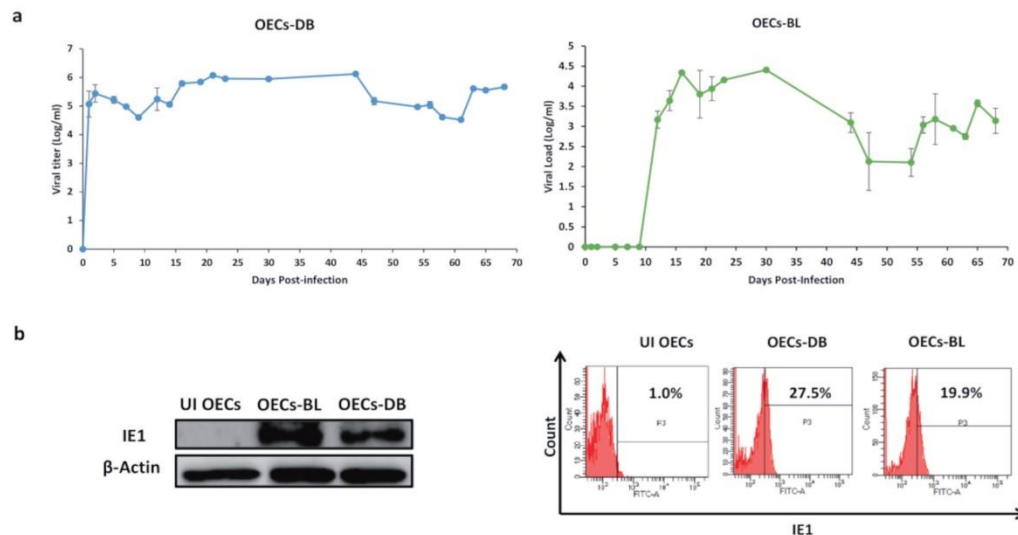

Human cytomegalovirus (HCMV) is a herpesvirus that infects between 40 and 95% of the worldwide population [6]. In healthy individuals, primary HCMV infection is asymptomatic. HCMV establishes a life-long chronic latency primarily in monocytes, tissue macrophages, and myeloid lineage CD34<sup>+</sup> hematopoietic progenitor cells, with periodic reactivation [7]. HCMV genomic variability could contribute to its oncomodulatory role where HCMV will encourage the development and spread of tumor cells [8, 9]. Lately, an oncogenic role of HCMV has been underlined

where the high-risk HCMV strains directly transform primary cells [10].

Polyploidy, a condition in which a normally diploid cell acquires additional sets of chromosomes, is formed via cell-cell fusion or endoreplication [11]. Polyploidy giant cancer cells (PGCCs) have been confirmed to possess cancer stem cell (CSC)-like characteristics, and give rise to progeny cells through asymmetric division which express epithelial-mesenchymal transition (EMT)-related markers thereby promoting invasion and migration [12–14]. Studies have shown that PGCCs generation was induced by anti-cancer therapies where the latter convert proliferating tumor into dormant cells [15]. The presence of PGCCs in OC has been preferentially reported in poor prognosis cancers participating in tumor relapse and therapy resistance [16]. Moreover, previous studies revealed the detection of PGCCs harboring HCMV; a significant correlation was shown between PGCCs presence and HCMV in breast cancer biopsies [17–20]. Besides PGCCs, tetraploidy has been reported in approximately 26% of solid tumors [21]; it's usually formed through cell fusion, endoreduplication, mitotic slippage, or cytokinetic failure, the latter two being the main mechanisms [21, 22]. It has been reported that tetraploid cells induce aneuploidy and transformation of mouse ovarian surface epithelial cells [23]. Aneuploidy post-tetraploidization is observed mainly in p53-inactivated cells [21]. p53 and telomerase depletion generates a state of chronic DNA damage, therefore, resulting in tetraploidization [21, 24].

**Fig. 1** Replication of high-risk HCMV strains in OECs cultures. **a** Time-course of the viral titer in the supernatant of OECs infected with HCMV-DB and BL as measured by IE1-qPCR. **b** Immunoblotting data of IE1 in uninfected OECs lysates and OECs infected with HCMV-DB and BL (day 5 post-infection).  $\beta$ -actin was used as loading control. IE1 expression by FACS in acutely infected OECs-DB and BL; UI OECs were used as a control.

Classical OC risk factors including age, family history, epigenetic as well as genetic alterations might generate a tumor-supporting cellular environment, where some oncogenic viruses reside and advance their oncogenic potential [1]. EZH2 dysregulation was associated with the development, progression, and therapeutic resistance of many tumors, particularly OC [25]. Several studies showed that EZH2 overexpression is associated with high-grade serous ovarian carcinoma (HGSOC) [25, 26]. Another study revealed that invading PGCCs possess strong EZH2 expression [27]. All in all, EZH2 potentially serves as an effective therapeutic target [25]. Moreover, there exists a strong emerging evidence showing HCMV infection prevalence in breast, cervical, colon, liver, prostate, and brain cancer patients [28–30]. HCMV-IE and pp65 proteins were detected in 82 and 97% of epithelial ovarian cancer, respectively [31]. Prominent HCMV-IE protein expression was linked to a higher stage of OC [31]. Further, CMV DNA was detected in 70% of cancerous ovarian tissues and was significantly higher compared to benign tumor cases [32]. Recent studies have identified high HCMV expression in OC biopsies that were associated with poor survival outcomes [33].

To investigate the potential role of HCMV infection in epithelial ovarian cancer, especially in HGSOC, human ovarian epithelial cells (OECs) were infected with low (KM and FS) and high-risk (DB and BL) oncogenic HCMV clinical strains; the latter previously transformed human astrocytes and human mammary epithelial cell [17, 30, 34]. In this study, we assessed the transforming potential of the two high-risk clinical strains, HCMV-DB and HCMV-BL, and investigated their molecular and cellular features that appeared in the long-term “CMV-transformed Ovarian cells” (CTO) cultures. Additionally, from HGSOC biopsies that revealed high EZH2 expression, we isolated three clinical HCMV strains that displayed oncogenic and stemness features when cultivated on OECs with enhanced EZH2 expression that could be curtailed by EZH2 inhibitors.

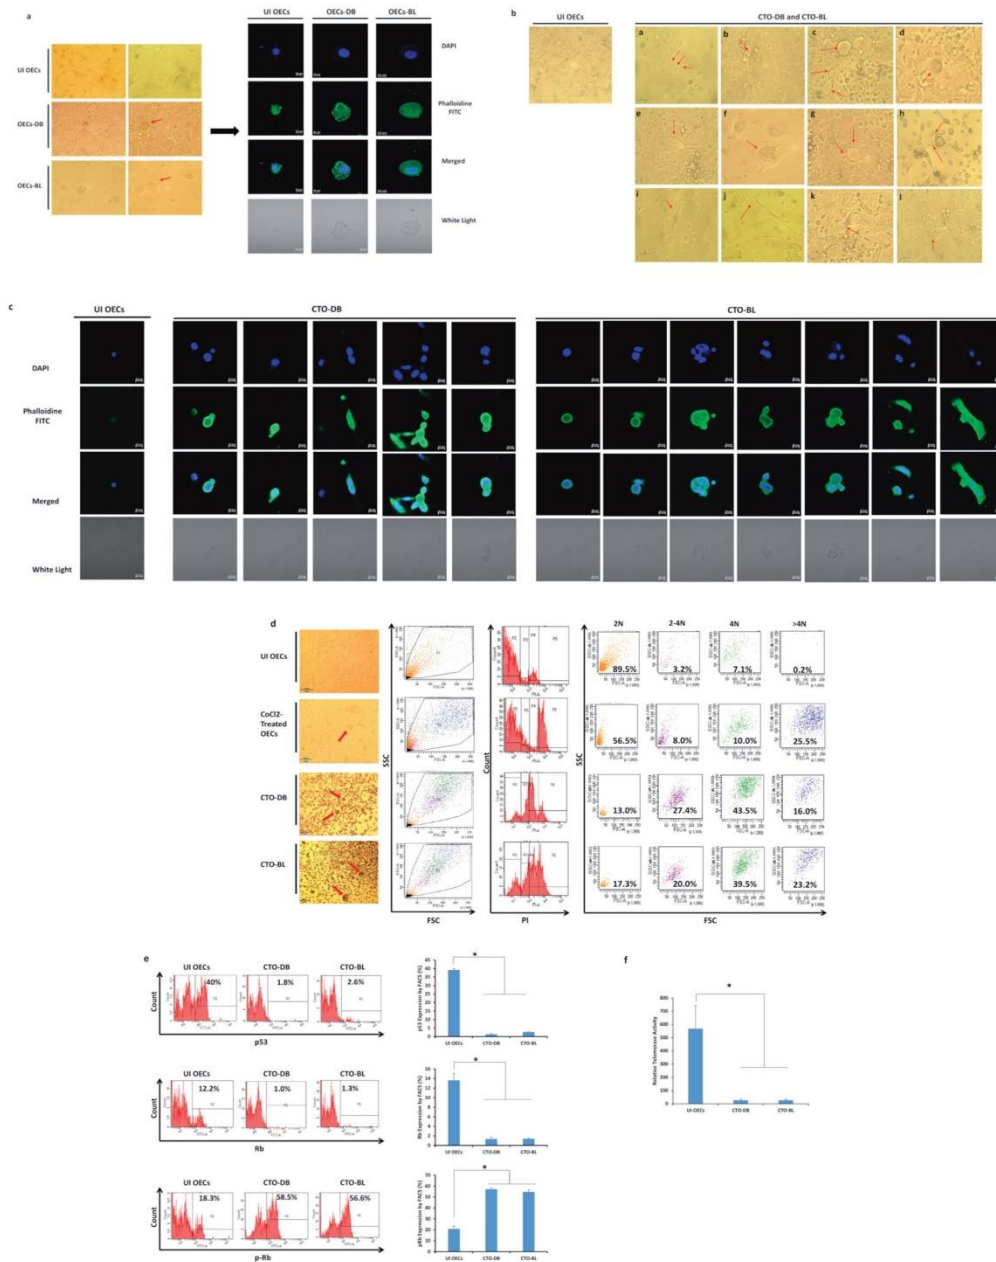

## RESULTS

### OECs chronically infected with HCMV-DB and BL strains generated CTO cells with PGCCs

Upon studying the tropism exhibited by HCMV in OECs, all HCMV clinical strains replicated showing a peak viral replication at day 21, 16, 16, and 19 post-infection in OECs infected with HCMV-DB, HCMV-BL, HCMV-KM, and HCMV-FS, respectively (Fig. 1a and Supplementary Fig. 1a). The peak level of HCMV productive infection was 6 and 4 logs in OECs-DB and BL, respectively (Fig. 1a). HCMV-IE1 and pp65 proteins were detected in OECs-DB and BL (Fig. 1b and Supplementary Fig. 2).

We noticed the existence of large-sized cells having large nuclei that were detected only in OECs chronically infected with the high-risk HCMV-DB and BL strains compared to uninfected OECs (Fig. 2a) and OECs chronically infected with HCMV-KM and FS strains (Supplementary Fig. 1b). Further, around three months post-infection, cellular survival was noted only in the chronically infected OECs-DB and BL compared to OECs-KM and FS (Supplementary Fig. 3). The emerging cells were termed “CMV-Transformed Ovarian epithelial cells” or CTO similar to the transformed cells that were previously reported by our group, namely, “CMV-Transformed Human mammary epithelial cells” or CTH cells and “CMV-Elicited Glioblastoma Cells” or CEGBCs [30, 34].

After applying a morphology-based classification, cellular heterogeneity was detected in CTO-DB and BL cultures including giant cells, blastomeres, blastocytes, multinucleated, mesenchymal cells, budding, and lipid droplets-rich cells as well as cells exhibiting filopodia and cytoplasmic vacuolization (Fig. 2b). Some of the aforementioned morphologies were further confirmed by confocal microscopy showing mainly multinucleated and mesenchymal cells, asymmetric division, budding, and cells with giant nuclei (Fig. 2c). A high percentage of tetraploidization and polyploidy cells was detected in CTO-DB and BL compared to UI OECs (Fig. 2d). CTO-DB and BL populations were classified into PGCCs ( $\geq 4N$ ), intermediate cells (ICs of 2–4N), and small cells (SCs of 2N) (Fig. 2d). As a positive control, cobalt chloride ( $\text{CoCl}_2$ ) was

used to induce PGCCs formation in OECs cultures (Fig. 2d, Supplementary Fig. 4).

Since the blockade of tumor suppressors and decreased telomerase activity have been correlated with tetraploidization

in several human cancers [24], p53 and Rb expression as well as telomerase activity were assessed in uninfected OECs, CTO-DB, and CTO-BL (Fig. 2e, f). Downregulation of p53 and Rb proteins was noticed in CTO-DB and BL compared to controls

**Fig. 2 Chronic infection of OECs with the high-risk HCMV clinical isolates and ploidy detection in OECs cultures.** **a** Microscopic images including confocal images of DAPI and phalloidine staining in OECs infected with HCMV-DB and BL; uninfected OECs were used as a negative control. Left panel: magnification  $\times 100$  and  $\times 200$ , scale bar 100 and 50  $\mu\text{m}$ ; Right panel: magnification  $\times 63$ , scale bar 10  $\mu\text{m}$ . Red arrows showing the PGCCs detected in OECs cultures. **b** The appearance of distinct cellular morphologies of the giant cell cycle including **(a)** filopodia, **(b, c, d)** blastomeres and blastocytes, **(e)** lipid droplets-filled cells, **(f)** multinucleated, **(g, h)** budding, **(i)** mesenchymal cells as well as **(j, k, l)** few atypical morphologies; magnification  $\times 100$ , scale bar 100  $\mu\text{m}$ . Uninfected OECs were used as a control. **c** Confocal microscopic images of DAPI and phalloidine staining in CTO-DB and BL. Uninfected OECs were used as a negative control; magnification  $\times 63$ , scale bar 10  $\mu\text{m}$ . **d** Propidium iodide (PI) staining for ploidy detection in HCMV-transformed OECs. Cobalt chloride (CoCl<sub>2</sub>)-treated OECs (450  $\mu\text{M}$ ) were used as a positive control. Microscopic images of uninfected OECs as well as the PGCCs generated in CTO-DB and BL cultures and post-CoCl<sub>2</sub> treatment; magnification  $\times 100$ , scale bar 100  $\mu\text{m}$ . **e** p53, Rb, and p-Rb expression in uninfected OECs and CTO-DB and BL by FACS. **f** Histograms representing the relative telomerase activity in uninfected OECs as well as CTO-DB and BL. Data are represented as mean  $\pm$  SD of two independent experiments. \* $p$ -value  $\leq 0.05$ .

( $p$ -value<sub>(UI OECs:CTO-HCMV)} = 0.03), unlike pRb which was upregulated in CTO-DB and BL ( $p$ -value<sub>(UI OECs:CTO-HCMV)} = 0.03) (Fig. 2e). Notably, telomerase activity was relatively low or undetectable in CTO-DB and BL compared to uninfected OECs ( $p$ -value = 0.03) (Fig. 2f). Hence, p53 and Rb downregulation along with decreased telomerase activity are sufficient to drive polyploidization in CTO-DB and BL, as previously reported [24].</sub></sub>

#### CTO cells display dedifferentiation, stemness, and EMT characteristics

CTO-DB and BL were seeded in soft agar to assess their oncogenic transforming potential. Colony formation was detected in the cultures seeded with CTO-DB and BL, compared to uninfected OECs (Fig. 3a). On the proteomic level, EZH2 and Myc upregulation was detected in CTO-DB and BL compared to uninfected OECs ( $p$ -value<sub>(UI OECs:CTO-HCMV)} = 0.03) (Fig. 3b–d); on the contrary, a limited EZH2 and Myc upregulation was observed in OECs-KM and FS ( $p$ -value<sub>(UI OECs:OECs-HCMV)} = 0.02) (Supplementary Fig. 1c). A significant positive correlation between EZH2 and Myc protein expression was detected in CTO cells ( $r = 0.983$ ,  $p$ -value  $< 0.001$ ) (Supplementary Fig. 5). Further, EZH2 and Myc transcripts were upregulated in CTO-DB and BL compared to uninfected controls ( $p$ -value<sub>(UI OECs:CTO-HCMV)} = 0.03) (Fig. 3e). Altogether, a remarkable EZH2 upregulation parallel to the limited increase in Myc expression was noticed in CTO infected with the high-risk HCMV-DB and BL strains. EZH2 and Myc were expressed mainly in the PGCCs subpopulation of CTO-DB and BL (Fig. 3g). A limited increase in SUZ12 expression was observed in CTO-DB and BL compared to uninfected OECs ( $p$ -value<sub>(UI OECs:CTO-HCMV)} = 0.03) (Supplementary Fig. 6a, b). Upon assessing the proliferative potential of OECs chronically infected with HCMV high-risk strains, Ki67Ag was highly prominent in CTO-DB and BL compared to uninfected OECs ( $p$ -value<sub>(UI OECs:CTO-HCMV)} = 0.03) (Fig. 3f). High Ki67Ag expression was detected in the large cells (Fig. 3g).</sub></sub></sub></sub></sub>

CTO-DB and BL displayed an embryonic stemness phenotype. The key regulatory genes maintaining the pluripotency and self-renewal properties of embryonic stem cells, Nanog, Sox2, and Oct4 were shown to be highly expressed in CTO-DB and BL compared to uninfected OECs (Fig. 4a, b, and Supplementary Fig. 7a). Additionally, transcripts of Nanog, Sox2, and Oct4 were elevated in CTO-DB and BL (Nanog,  $p$ -value<sub>(UI OECs:CTO-HCMV)} = 0.06; Sox2 and Oct4,  $p$ -value<sub>(UI OECs:CTO-HCMV)} = 0.03) (Fig. 4c and Supplementary Fig. 7b). Besides PGCCs appearance in CTO-DB and BL cultures, it's worth mentioning the appearance of spontaneous spheroids in CTO-BL cultures (Fig. 4d). Further, in the presence of methylcellulose, spheroids were generated in CTO-DB and BL cultures (Fig. 4e). Finally, CD44, a marker of stemness and invasiveness, was upregulated in CTO-DB and BL cultures compared to uninfected OECs (Supplementary Fig. 8).</sub></sub>

EMT fuels cancer progression, tumor cell invasion, and therapy resistance [35]. PGCCs gain strong invasiveness and migration ability after they undergo EMT [36]. Vimentin was strongly upregulated in DB and BL-infected OECs ( $p$ -value<sub>(UI OECs:CTO-HCMV)} = 0.03), whereas a slight decrease in E-cadherin was noticed compared to uninfected OECs ( $p$ -value<sub>(UI OECs:CTO-HCMV)} = 0.06) (Fig. 5a–c). Vimentin and</sub></sub>

E-cadherin were expressed mainly in the PGCCs and ICs subpopulations of CTO-DB and BL (Fig. 5d). Altogether, the co-existence of vimentin and E-cadherin was detected in CTO-DB and BL, indicating a mesenchymal/epithelial hybrid state that was also accompanied with occasionally existing small cells possessing an elevated E-cadherin expression (Fig. 5 and Supplementary Fig. 9). The co-existence of mesenchymal and epithelial phenotypes confirms the cellular plasticity of CTO-DB and BL. As a control, EZH2, Myc, Ki67Ag, Vimentin, E-cadherin, and CD44 protein expression in the subpopulations of uninfected OECs was provided in Supplementary Fig. 10.

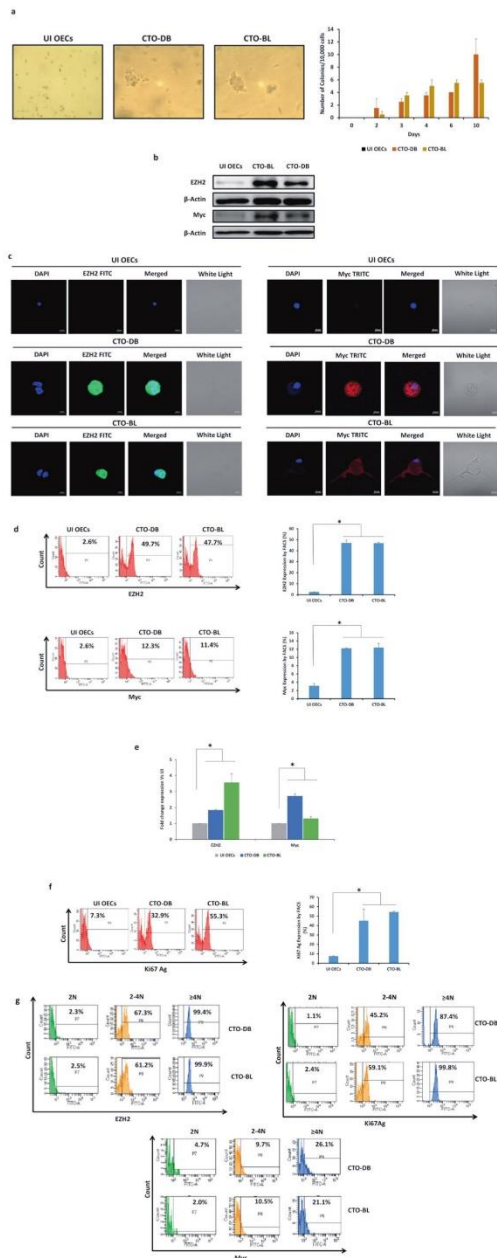

#### Lytic and latent HCMV replication in transformed OECs

Sustained HCMV replication was confirmed in OECs chronically infected with HCMV-DB and BL, namely CTO-DB and BL (Fig. 6). IE1 protein was remarkably detected in CTO-DB and BL versus uninfected OECs (Fig. 6a, b); elevated IE1 expression was detected mainly in the PGCCs subpopulation compared to ICs and SCs (Supplementary Fig. 11). IE1 and UL69 genes and transcripts were detected in CTO-DB and BL compared to uninfected OECs (Fig. 6c, d), indicating lytic HCMV replication. In addition, HCMV latency in CTO-DB and BL cultures was established by IE1 reactivation that was observed post-TPA treatment ( $p$ -value<sub>(CTO:TPA treated CTO)} = 0.02) (Fig. 6e and Supplementary Fig. 12).</sub>

Given that EZH2 is considered a major tumor marker and an effective therapeutic target for OC, herein, we evaluated the impact of two EZH2 inhibitors (GSK343 and EPZ6438) on CTO proliferation and polyploidization. Upon EZH2 blockade (Supplementary Fig. 13), detection of HCMV-IE1 gene was suppressed (Fig. 6f). Ki67Ag protein expression was decreased post-EZH2 inhibitor treatment of CTO-DB and BL compared to untreated CTO cells ( $p$ -value<sub>(CTO:EZH2 inhibitors treated CTO)} = 0.004) (Fig. 6g). Upon assessing the PI expression in the subpopulations of CTO cells, GSK343 and EPZ6438 reduced tetraploidization and polyploidization in treated CTO cells compared to controls ( $p$ -value<sub>(CTO:EZH2 inhibitors treated CTO)} = 0.007 and 0.004, respectively) (Fig. 6h).</sub></sub>

#### EZH2 upregulation in HCMV-positive HGSOC biopsies and the isolation of three oncogenic HCMV strains from EZH2<sup>High</sup> HGSOC biopsies

To further assess the role of HCMV, EZH2, and PGCCs induction in vivo, we analyzed 25 OC biopsies (HGSOC biopsies  $n = 18$  and adjacent non-tumoral biopsies  $n = 7$ ) (Supplementary Table 3) for the presence of HCMV, PGCCs count, as well as EZH2, Myc, and Akt expression (Fig. 7, Supplementary Fig. 14, and Supplementary Fig. 15). PGCCs with giant or multiple nuclei were detected in the HGSOC biopsies (Fig. 7a). HCMV was detected in 72% of HGSOC biopsies (Fig. 7b). Elevated PGCCs count was mainly detected in HCMV-positive HGSOC biopsies (Fig. 7c). HCMV-positive tumor biopsies displayed mostly an enhanced EZH2 and Akt with a limited Myc expression (Fig. 7d, Supplementary Fig. 14, and Supplementary Fig. 15a). A significant positive correlation was found between HCMV presence and EZH2 as well as Akt expression ( $r = -0.598$ ,  $p$ -value = 0.009 and  $r = -0.466$ ,  $p$ -value =

0.05, respectively, based on Ct values) (Fig. 7e and Supplementary Fig. 15b). A significant positive correlation was detected between Akt expression and EZH2 as well as Myc expression ( $r = 0.420$ ,  $p$ -value = 0.015 and  $r = 0.620$ ,  $p$ -value = 0.006, respectively)

**Fig. 3** Colony formation in soft agar and the phenotypic characterization of HCMV-transformed OECs. **a** Colony formation in soft agar seeded with CTO-DB and BL (MOI = 1); UI OECs were used as a negative control. Formed colonies were observed under an inverted light microscope (Magnification  $\times 200$ , scale bar 50  $\mu\text{m}$ ). Histogram representing the colony quantification/10,000 cells over days. **b** Immunoblotting data of EZH2 and Myc in uninfected OECs lysates and CTO-DB and BL.  $\beta$ -actin was used as loading control. **c** Confocal microscopic images of EZH2, Myc, and DAPI staining in CTO-DB and BL. UI OECs were used as controls; magnification  $\times 63$ , scale bar 10  $\mu\text{m}$ . **d** FACS staining of EZH2 and Myc in uninfected OECs as well as CTO-DB and BL. **e** EZH2 and Myc transcripts detection by RT-qPCR. **f** FACS staining of Ki67Ag in uninfected OECs as well as CTO-DB and BL. **g** EZH2, Myc, and Ki67Ag expression in CTO-DB and BL subpopulations (2N, 2–4N, and  $\geq 4$ N). Data are represented as mean  $\pm$  SD of two independent experiments. \* $p$ -value  $\leq 0.05$ .

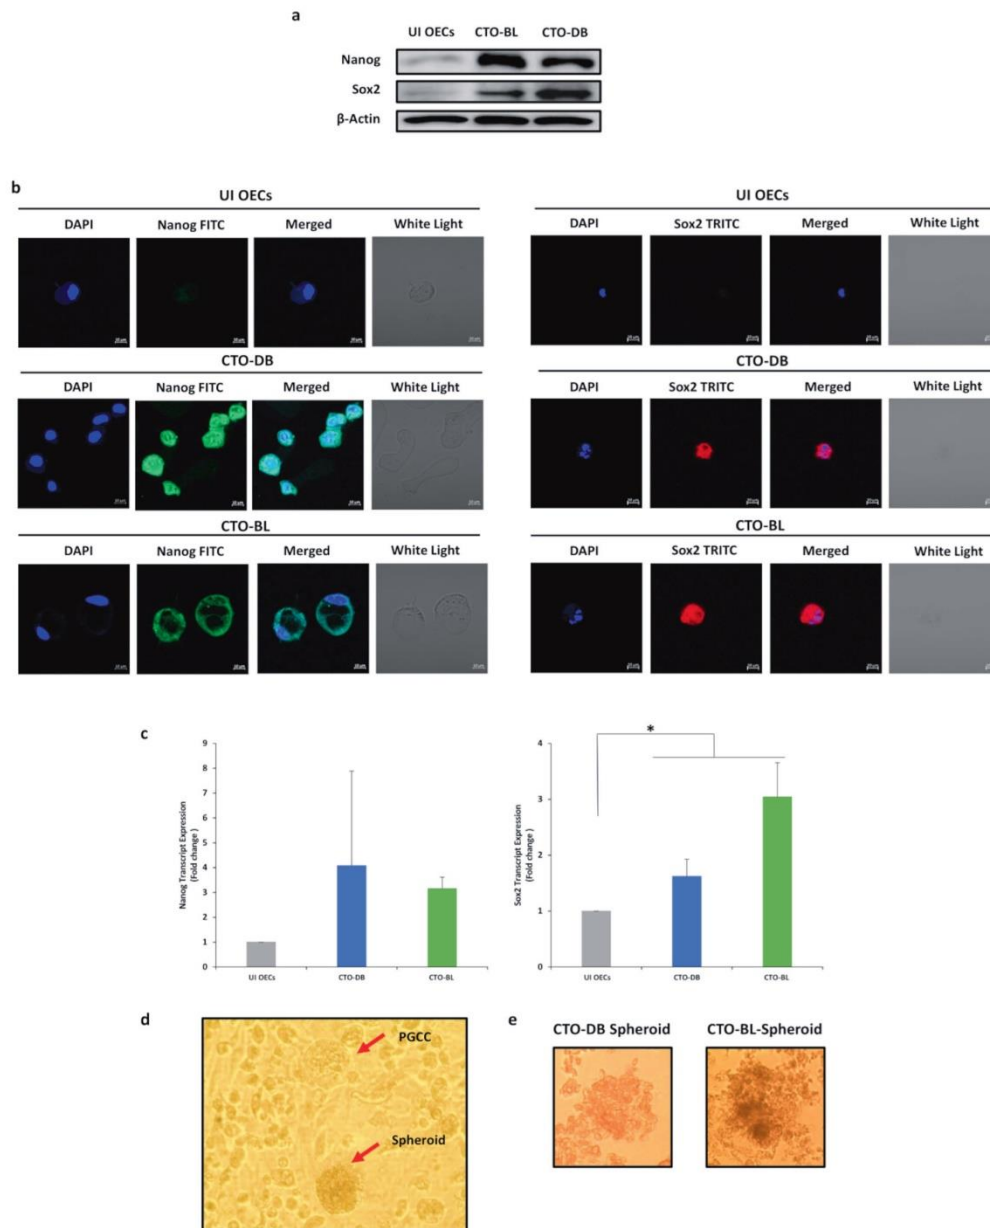

(Supplementary Fig. 15b). Among the eighteen HCMV-positive HGSOB biopsies, three biopsies with the highest EZH2 expression were considered for HCMV isolation. The three HCMV-OC strains were isolated by tissue disruption and filtration, and were subsequently grown in MRC5 cells showing a peak of viral load of 3 logs around day 7 post-infection (Fig. 7f). Following OECs infection with the three HCMV-OC strains, HCMV presence was confirmed by the detection of IE1 gene in addition to the morphological changes that appeared in the OECs infected cultures, for instance, giant and multinucleated cells showing cell budding as well as mesenchymal cells (Fig. 7f, g). Post-EZH2 inhibition, using GSK343, no HCMV replication was detected in addition to the absence of morphological heterogeneity in the infected cultures (Fig. 7g, h). Upregulation of Ki67Ag, EZH2, and Myc expression was observed in CTO-HCMV-OC compared to uninfected OECs and GSK-treated CTO-HCMV-OC cells (Ki67Ag  $p$ -value (CTO:GSK343-CTO) = 0.01; EZH2  $p$ -value (CTO:GSK343-CTO) = 0.002; Myc  $p$ -value (CTO:GSK343-CTO) = 0.002) (Fig. 7i). GSK343 reduced Ki67Ag, EZH2, and Myc expression by 56%, 79%, and 63%, respectively (Fig. 7i). EZH2 inhibition reduced PGCCs percentage in infected cultures compared to untreated CTO cells ( $p$ -value = 0.002) (Fig. 7j).

## DISCUSSION

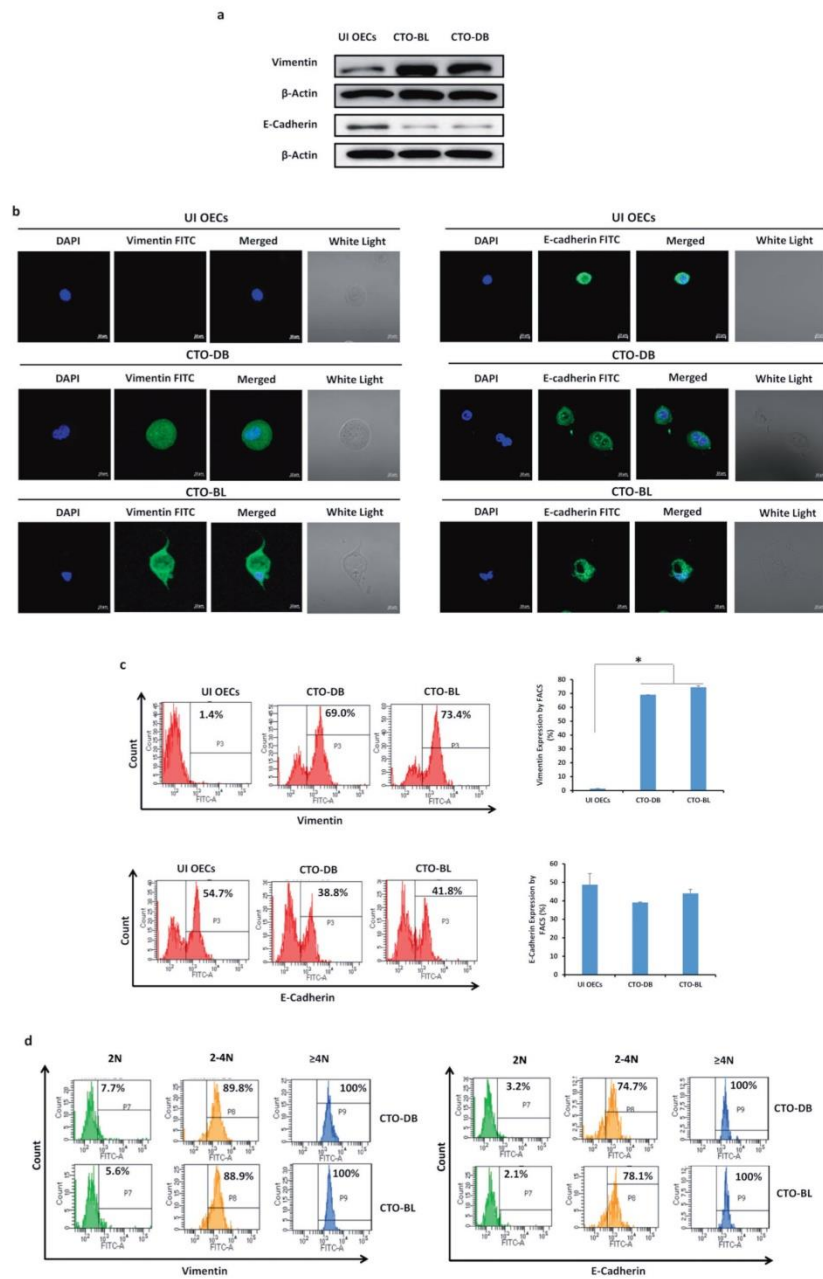

In the present study, we assessed the potential transforming capacities of the high-risk HCMV-DB and BL strains, following the OECs infection. The OECs infection with the high-risk HCMV-DB and BL strains resulted in a pro-oncogenic cellular environment and sustained growth of CMV-transformed OECs with soft agar colonies formation. The CTO cells dedifferentiated, displayed stemness as well as EMT-MET hybrid phenotype, and finally resulted in PGCCs generation (Fig. 8) and spheroid formation. HCMV presence accompanied by polyploidy, EZH2 upregulation, and malignant phenotype potentially confirm the transformation process. In vivo, 72% of HGSOB biopsies were found to harbor HCMV with elevated PGCCs count as well as enhanced EZH2 expression, revealing a strong correlation between HCMV, PGCCs, and EZH2 expression. Three HCMV-OC strains were isolated from EZH2<sup>high</sup> OC tumors that transformed OECs toward CTO possessing increased EZH2, Ki67Ag, and Myc expression parallel to polyploidy induction. The expression of the aforementioned markers and polyploidy were curtailed by EZH2 inhibitors therapy.

PGCCs play a fundamental role in tumor progression and in regulating tumor heterogeneity [37, 38]. Accumulating evidence reveals the presence of PGCCs in OC, particularly the HGSOB, where PGCCs act as stem-like, self-renewing cells that are considered prognostic factors for OC [38, 39]. In our study, CTO cells generated PGCCs, and were heterogeneous showing distinct

morphological features including budding, filopodia, lipid droplets-filled cells, blastomere-like cells, and multinucleated cells that were previously detected in OC especially HGSOc [13, 37, 40–44] and reported upon HCMV infection of human

mammary epithelial cells [17–19]. Our findings indicated that polyploidy harboring HCMV might induce the acquisition of a malignant phenotype via the giant cell cycling [14]. p53 and Rb inactivation have been correlated with tetraploidization in human

tumors [22]. Indeed, p53 was shown to be mutated in more than 50% of human tumors, especially HGSOc; most of the p53 mutations acquired an oncogenic function. It's worth mentioning that tumor-promoting viruses reduce p53 activity [45]. Studies have shown that the incidence of tetraploidy occurs in p53-deficient cells possessing prolonged DNA damage due to persistent telomere dysfunction [46]. p53 and Rb expression was decreased in CTO-DB and BL that showed high percentages of tetraploidization and decreased telomerase activity, in line with the telomere-driven tetraploidization induced by critically short telomeres with the potential to promote tumorigenesis in early cancerous lesions [24]. Several HCMV products have been involved in the cellular transformation including IE1, IE2, pp65, US28, cmvIL-10, UL76, UL44, and UL84, etc. Such expression of HCMV gene products could impair the pathways of p53 and Rb [6, 8]. HCMV-IE1, IE2, and UL97 allow the evasion of p53 and Rb [8]. Hence, the impaired p53 and Rb pathways in CTO cells were due to the transforming potential of HCMV contrasting the Ras, human telomerase reverse transcriptase (hTERT), and SV40-mediated transformation of human ovarian cells [47].

Numerous biomarkers have become essential in characterizing and managing ovarian cancers [48]. EZH2, a downstream target of Myc oncogene, has been involved in regulating cell cycle progression [49]. Elevated EZH2 activity has been reported in approximately 85% of epithelial ovarian carcinomas [50]. Since EZH2 enhances cell proliferation, inhibits apoptosis, promotes angiogenesis, metastasis and therapy resistance in OC [50, 51], inhibiting EZH2 suggests an effectual strategy for developing OC therapies. A study reported that EZH2 degradation profoundly blocked ovarian tumor cell proliferation and tumorigenesis in vitro and in vivo [52]. Given the recent approval of the EZH2-targeting agent (tazemetostat) by the FDA as a treatment for follicular lymphoma, enhanced therapies may soon be available for suppressing ovarian cancers [50]. A combination of EZH2 inhibitor, PARP inhibitor, and/or immune checkpoint blockers might be synergistic in ovarian cancers [53, 54]. In line with the critical role of EZH2 in epithelial ovarian cancer [25], EZH2 overexpression was detected in CTO-DB and BL compared to uninfected OECs. EZH2 inhibition restricted the proliferation potential of CTO cells and limited tetraploidization. Moreover, Myc, as a transcription factor, plays an essential role in regulating multiple cellular processes. Enhanced Myc expression and/or mutated Myc have been reported in most human cancers and have been observed in 20–50% of ovarian carcinoma [55, 56]. A limited expression of Myc was detected in the PGCCs population of HCMV-infected OECs, reinforcing the emerging data on limited Myc expression in dormant cells [57]. EZH2 upregulation was shown to be the main feature in CTO cells and ovarian epithelial cancers. Anti-EZH2 treatment makes EZH2 a desirable therapeutic target, unlike anti-Myc therapeutics. Given the absence of enzymatic activity and the lack of surface domains specific for most pharmacological inhibitors, Myc is considered an “undruggable” protein [55], hence anti-Myc therapeutics might fall short of expectations in limiting ovarian cancers.

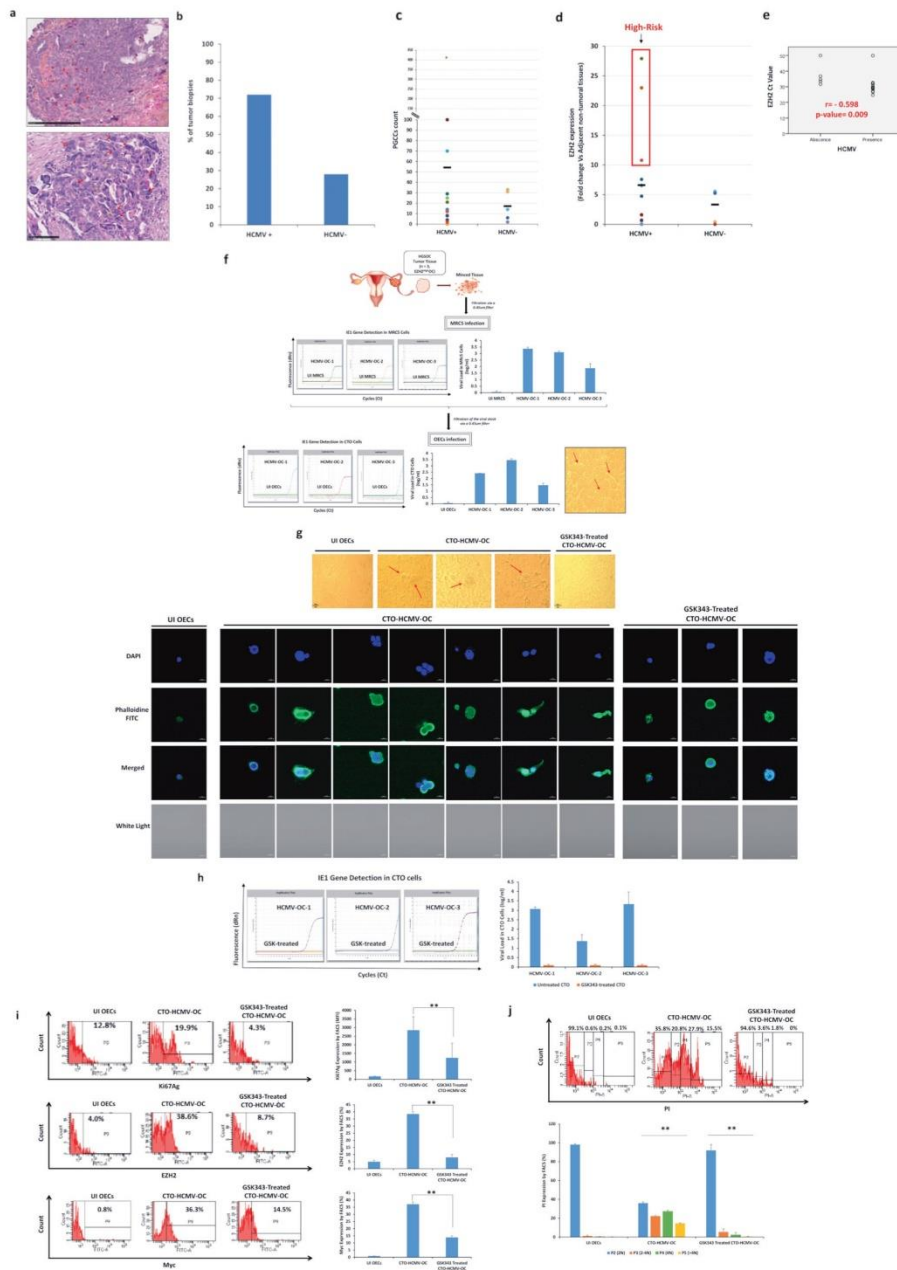

Cells possessing sphere-forming potentials were shown to reside in the malignant ascites of OC patients [58–60]. In OC, the aforementioned cells are strong contributors to tumor progression, metastasis, chemotherapy resistance, and disease relapse [59]. The spontaneous spheroid generation along with the high

expression of Nanog and Oct4 in CTO-DB and BL is in line with the previously described OC cell phenotype [61]. Given their role in maintaining pluripotency and long-term self-renewal, the embryonic transcription factors Oct4 and Nanog are recognized as part of the stem cell signature that strongly correlates with spheroid formation, tumor initiation, and chemoresistance in ovarian cancer cells [61, 62]. CD44 was highly expressed in CTO-DB and BL cells; it has been previously shown to drive the progression of several tumors [63, 64], maintain stem cell quiescence, and promote EMT in OC [65]. Further, CD44 has been linked to the sphere-forming, self-renewing and tumor-initiating potential of OC cells [66]. The co-existence of vimentin and E-cadherin in CTO-DB and BL highlights the high cellular plasticity. EMT plasticity with EMT and MET alternately taking place was revealed during HGSOc progression where cells co-express epithelial and mesenchymal determinants [44, 67, 68]. Besides cellular plasticity, the hybrid E/M state promotes stem-like properties as well as metastatic and tumorigenic potential [69, 70].

Upon infecting OECs with HCMV-DB and BL strains, IE1 and pp65 proteins were detected which is in line with the recent studies that have identified high expressions of HCMV-IE or pp65 in ovarian tumor samples that were associated with poor survival outcomes [1, 33], suggesting that HCMV infection could potentially promote cancer progression. All in all, HCMV-induced EZH2 expression along with the embryonic stem-like phenotype and cellular plasticity in the IE1-expressing OECs/CTO cells could establish a significant model in the context of OC. Several studies shed light on the existence of herpesviruses DNA and proteins in ovarian tissues that may hold potential in the process of OC tumorigenesis [1, 33, 71]. Herein, we reported the detection of HCMV in HGSOc biopsies displaying elevated PGCCs count as well as enhanced EZH2 expression. It is worth mentioning that, neither HPV nor EBV was detected in the eighteen tested HGSOc biopsies.

Three HCMV strains with a strong transforming potential, so called high-risk strains, were isolated from EZH2<sup>High</sup> HGSOc biopsies. After OECs infection, CTO cells were generated with morphological features matching the previously described CTO-DB and BL. Additionally, we evaluated EZH2 expression in the high-risk HCMV strains that were recovered directly from HGSOc biopsies thereby assessing their oncogenic and stemness potential. Unlike GSK-treated CTO, the expression of EZH2, Myc, and Ki67Ag was predominantly elevated in untreated CTO-HCMV-OC cells parallel to the PGCCs appearance. In summary, HCMV clinical strains reside in HGSOc biopsies retaining cancer-promoting potentials.

The high-risk HCMV strains that were isolated from HGSOc, TNBC, and GBM patients shared the same transforming potential [17, 30, 34]. PGCCs were detected in the aforementioned cell cultures that were shown to highly express Myc and EZH2 pointing toward a potential link between HCMV, PGCCs, EZH2, and Myc. CTO and CTH cells dedifferentiated and revealed stemness as well as EMT traits [17, 19, 34]. On the other hand, CEGBCs dedifferentiated and displayed stemness, PMT as well as invasiveness features [30]. The phenotypic changes were similar in HCMV-infected ovarian and mammary epithelial cells. However, the difference was mainly the detection of high percentages of tetraploid cells in the CTO cultures compared to the  $>4N$  population detected in CTH cells. In both models, a high degree of cellular plasticity was detected knowing that

ovarian and mammary epithelial cells are isolated from human glandular organs.

Given that cancer patients with lower HCMV activity have a better prognosis, targeting HCMV might have a vital role in treating OC

[33]. Post-anti-CMV therapy, a remarkably high extended survival was observed in both newly diagnosed and recurrent glioblastoma patients [72]. Current vaccine candidates have focused on several HCMV antigens/epitopes such as gB, gH, pentamer complex, pp65

**Fig. 7 HCMV detection, PGCCs presence as well as EZH2 expression in ovarian cancer biopsies.** **a** Ovarian cancer tissue HES staining; magnification  $\times 400$ , scale bar  $250\ \mu\text{m}$  (upper panel) and  $100\ \mu\text{m}$  (lower panel). and IE1 [73, 74]. Recently, CMV-specific immunotherapy including cytotoxic T lymphocyte (CTL) or dendritic cell (DC)-based vaccines has contributed to minimal successful outcomes in glioblastoma treatment [74, 75]. In addition, using EZH2 inhibitors to specifically target ovarian tumors could ultimately improve patients outcomes [25]. Two inhibitors triggering EZH2 degradation (DZNep and YM281) exhibited potent efficacy in OC cell lines and xenografts [52]. GSK343 significantly induced apoptosis and inhibited the invasion of ovarian epithelial cells in 3D cultures which more closely mimics the tumor microenvironment *in vivo* [76]. In patient-derived glioma stem cells, GSK343 was shown to suppress the stemness traits [77]. Interestingly, in the present study, EZH2 inhibitors totally blocked HCMV replication (Figs. 6f and 7h). It's worth noting that the HCMV major immediate early promoter (MIEP) transcriptional repressor, growth factor independence1 (GF11), is controlled by the EZH2-NDY1/KDM2B-JARID2 axis. Therefore, EZH2 inhibitors might result in an enhanced GF11 expression which could block viral replication [78]. Hence, combinational therapies including EZH2 inhibitors may prove to be a promising milestone in developing therapeutic strategies for ovarian cancer treatment.

## CONCLUSION

In conclusion, our data indicated that the high-risk HCMV strains which triggered EZH2 upregulation can induce polyploidy, OECs dedifferentiation, stemness, and EMT/MET characteristics parallel to the existence of giant cell cycling. Future studies, with more detailed analyses, may establish new avenues to understand the complex pathogenesis of OC and might pave the way for novel targeted therapies.

## MATERIAL AND METHODS

### Cell cultures

Human ovarian surface epithelial cells (HOSE cells or OECs, as mentioned in our study) and human embryonic lung fibroblasts (MRC5 cells) were purchased from Innoprot (Derio, Spain) and RD-Biotech (Besançon, France), respectively. OECs were cultivated in ovarian epithelial cell medium (serum-free) supplemented with ovarian epithelial cell growth supplement (OEpiCGS) and penicillin/streptomycin solution (P60132, Innoprot). MRC5 cells were cultivated in Dulbecco's modified Eagle medium (Sigma-Aldrich, Saint-Louis, MO) supplemented with 10% fetal bovine serum (Dutscher, Bernolsheim, France) and penicillin (100 U/mL)-streptomycin (100  $\mu\text{g}/\text{mL}$ ) (Life Technologies, Eugene, OR). Cells were cultured under standard conditions (37 °C, 5% CO<sub>2</sub>, 95% humidity). To note that, HOSE cells or OECs were isolated from healthy human ovaries, as mentioned in the technical data sheet (P10982, Innoprot). Cultures were verified as mycoplasma-free as determined by monthly screenings (VenorGem classic mycoplasma detection, Minerva Biolabs).

### Characterization of HCMV clinical isolates

Clinical HCMV strains, namely HCMV-DB (GenBank KT959235), BL (GenBank MW980585), KM, and FS were isolated from patients that were hospitalized at Besançon University Hospital (France) as previously described [19, 34]. Cell-free virus stocks and infections were performed as previously detailed. It is worth mentioning that careful screening of our viral stocks was conducted to rule out the presence of other oncoviruses [19].

## Viral growth and detection

Infections of OECs, quantification of viral replication, and HCMV detection were performed as previously described [19]. OECs ( $1 \times 10^6$ ) infection with the clinical isolates was performed at a multiplicity of infection (MOI) of 1. For HCMV quantification, cell-free infectious supernatant was collected, DNA was isolated (EZNA Blood DNA Kit, D3392-02, Omega BIO-TEK, Norcross, GA) and real-time IE1 quantitative PCR (qPCR) was performed using KAPA SYBR FAST Master Mix (KAPA BIOSYSTEMS, Potters Bar, UK) and IE1 and UL69 primers. Real-time qPCR reactions were activated at 95 °C for 10 min and then 50 cycles (15 s at 95 °C and 1 min at 60 °C) were conducted using a Stratagene Mx3005P thermocycler (Agilent Technologies, Santa Clara, CA). Results collection and analysis were done using MxPro qPCR software. Primers used are listed in Supplementary Table 1.

## Western blotting

IE1, pp65, Myc, EZH2, Sox2, Nanog, E-cadherin, and vimentin expression in uninfected OECs, HCMV-infected OECs and CTO cells was assessed as described previously [34].  $\beta$ -actin was used as a loading control. Antibodies used are supplied in Supplementary Table 2.

## Flow cytometry analysis

Cells ( $1 \times 10^5$ ) were collected from uninfected OECs, HCMV-infected OECs and CTO cells. Cells were fixed, permeabilized, and stained as previously reported [19]. Cytofluorometric analysis was achieved using a BD LSRFortessa X-20 (BD Biosciences) flow cytometer. FACSDiva software (BD Biosciences) was used for data collection and analysis. The antibodies used are provided in Supplementary Table 2. For cell cycle analysis, uninfected OECs or CTO cells were washed in 1X PBS, fixed in 70% ethanol, and resuspended in 50  $\mu\text{g}/\text{mL}$  propidium iodide (P3566, life technologies, Eugene, USA) with 0.1 mg/mL RNase (R4642, Sigma-Aldrich, Saint-Louis, MO, USA), then incubated at 37 °C for 30 min as described previously [17].

## Assessment of telomerase activity

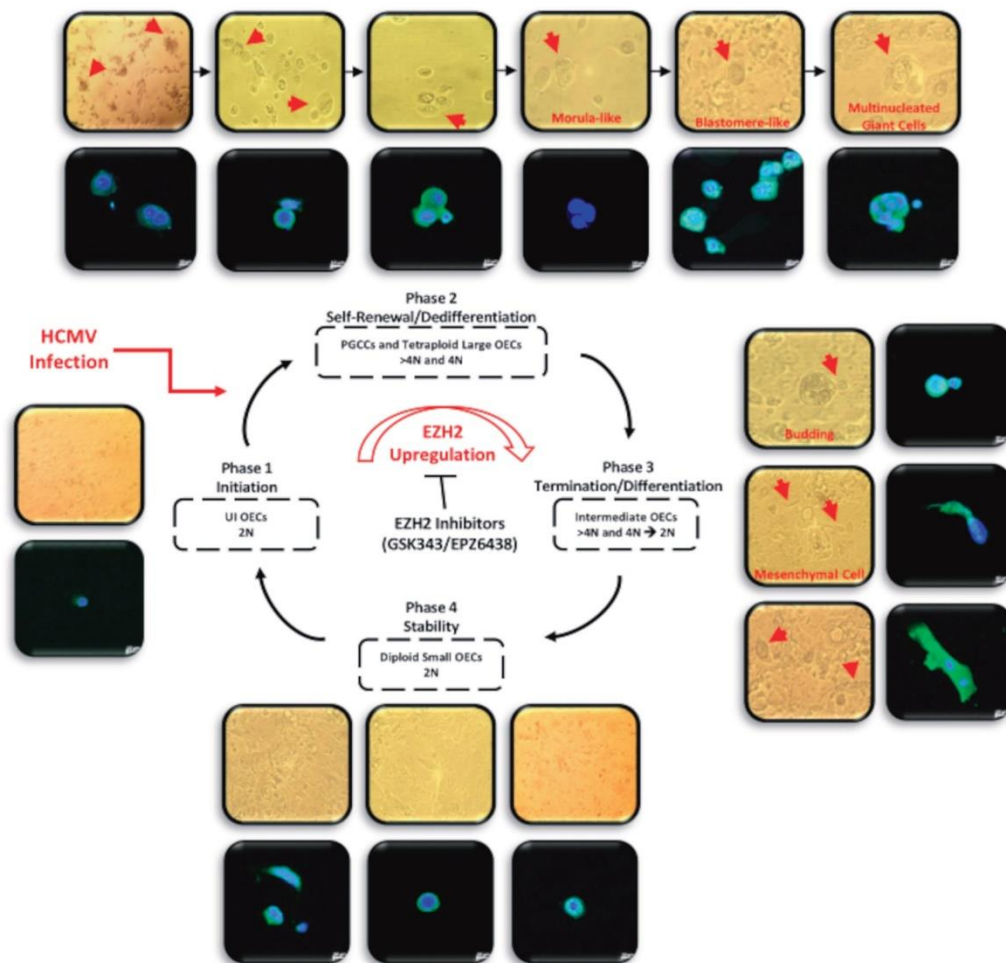

Uninfected OECs and CTO cells were collected, washed with PBS, and resuspended in RIPA lysis buffer and 4% protease inhibitor on ice for 30 min. Samples were then centrifuged at 16,000 g for 30 min at 4 °C and the protein concentration was determined using Bradford assay (DC Protein Assay kit, Bio-Rad Laboratories, Hercules, CA). Telomerase activity was assessed as described previously and according to the manufacturer's instructions [19].

## Reverse transcription quantitative polymerase chain reaction (RT-qPCR)

The detection of IE1, UL69, EZH2, Myc, Sox2, Nanog, and Oct4 transcripts was assessed by RT-qPCR as detailed previously [79]. Briefly, total RNA was extracted using E.Z.N.A. Total RNA Kit I (Omega Bio-Tech, GA, USA), and reverse transcription was performed using the SuperScript IV First-Strand Synthesis kit (Invitrogen, Carlsbad, CA, USA). The expression of markers was measured by real-time qPCR using a KAPA SYBR FAST Master Mix (KAPA BIOSYSTEMS, KK4601) and specific primers according to the manufacturer's protocol. Primers used are listed in Supplementary Table 1.

## Confocal microscopy

Confocal microscopy of uninfected and HCMV-infected OECs as well as spheroids was performed as previously detailed [19]. The antibodies used are provided in Supplementary Table 2.

**Fig. 8** A schematic representing the giant cell cycling following HCMV infection of OECs. Giant cell cycle representing four distinct phases including initiation, self-renewal, termination and stability. Upon HCMV infection, the 2N OECs go into the initiation phase through endoreplication. Polyploid cells (> 4N) and tetraploid cells (4N) generate in the self-renewal/dedifferentiation stage due to HCMV infection and the subsequent EZH2 upregulation. Cell budding takes place from multinucleated or mononucleated giant cells generating intermediate 2–4N OECs during the termination/differentiation phase. Intermediate OECs gradually reach stability and are converted into diploid small OECs (2N).

#### Soft agar colony formation assay

Colony formation in soft agar (Colorimetric assay, CB135; Cell Biolabs Inc., San Diego, CA) seeded with uninfected and HCMV-infected OECs was performed as previously described [19].

#### Spheroid formation assay

Spheroids of OECs were prepared as described previously [80]. Single cells ( $1 \times 10^4$ ) isolated by accutase were seeded in a serum-free OECs medium containing methylcellulose.

#### EZH2 inhibition assay

CTO-DB and BL were treated with 0.1  $\mu$ M of two EZH2 inhibitors (GSK343 and EP26438). Treatment was renewed every 2 days. Ki67Ag and EZH2

expression by FACS was assessed in treated and untreated CTO cells. HCMV-IE1 gene detection was detected in the supernatants of treated and untreated CTO cells.

#### Ovarian cancer biopsies

Ovarian biopsies ( $n=25$ ; HGSOC biopsies  $n=18$ , and adjacent non-tumoral biopsies  $n=7$ ) were provided by the Regional tumor bank (BB0033-00024 Tumorothèque Régionale de Franche-Comté). Clinical data and treatments of the OC patients were provided in Supplementary Table 3. A written informed consent for participation was obtained from all patients. The study was authorized by the local ethics committees of Besançon University Hospital (Besançon, France) and the French Research Ministry (AC-2015-2496, CNIL n°1173545, NF-5-138 96900 n°F2015).

Genomic DNA was isolated from patient biopsies, and HCMV presence was identified by qPCR using specific primers against IE1 and UL69 genes. RNA was extracted from the biopsies and reverse transcription was performed as reported previously [17, 79]. Expression of EZH2, Myc, Akt, and  $\beta$ -2-Microglobulin was assessed by real-time qPCR using specific primers according to the manufacturer's protocol. Fold change expression in OC biopsies versus adjacent non-tumoral biopsies was calculated using the delta-delta Ct method [17, 79]. Neither human papillomavirus (HPV) nor Epstein-Barr virus (EBV) was detected in the ovarian cancer biopsies. Primers used are listed in Supplementary Table 1. PGCCs presence in HGSOc biopsies was confirmed by hematoxylin and eosin staining; briefly, PGCCs were counted in five hot spots of each tumor sample (magnification  $\times 400$ , field diameter of 250  $\mu$ m and 100  $\mu$ m, Zeiss AxioStar). Three HCMV-OC strains were isolated from HGSOc biopsies.

#### Statistical analysis

Quantitative results are reported as mean  $\pm$  SD of independent experiments. Statistical analyses were done using Wilcoxon and Mann-Whitney tests; a  $p$ -value  $\leq 0.05$  was considered to be statistically significant [\*]:  $\leq 0.05$ ; \*\*,  $\leq 0.01$ ; \*\*\*,  $\leq 0.001$ ). Correlation analysis was done using Spearman, Pearson, and Kendall's Tau correlation tests. Microsoft Excel was used to construct the plots and histogram data.

#### DATA AVAILABILITY

The data supporting the findings of this study are available within the article and its Supplementary information files and from the corresponding authors on request.

#### ACKNOWLEDGEMENTS

This work was supported by grants from the University of Franche-Comté (UFC) (CR3300), the Région Franche-Comté (2021-Y-08292 and 2021-Y-08290) and the Ligue contre le Cancer (CR3304) to Georges Herbein. REB is a recipient of a doctoral scholarship from Apex Biosolutions. SHA is supported by ANR (Agence Nationale pour la Recherche) grant. We thank Apex Biosolutions for financial support. The funders had no role in the data collection, analysis, patient recruitment, or decision to

publish. The authors thank DImaCell Imaging Ressource Center, University of Bourgogne Franche-Comté, Faculty of Health Sciences, 25000 Besançon, France for technical support.

#### AUTHOR CONTRIBUTIONS

Conceptualization, GH; formal analysis, REB, SHA, RM, FM, FB, GH; investigation, REB, SHA, FM, RM; writing—original draft preparation, REB, SHA, GH; writing—review and editing, REB, SHA, GH; directly accessed and verified the underlying data: REB, SHA, GH; visualization, REB, SHA, GH; supervision, GH; project administration, GH; funding acquisition, GH. All authors have read and agreed to the published version of the manuscript.

#### COMPETING INTERESTS

The authors declare no competing interests.

#### INSTITUTIONAL REVIEW BOARD STATEMENT

The study was conducted according to the guidelines of the Declaration of Helsinki. A written informed consent for participation was obtained from all patients. The study was authorized by the local ethics committees of Besançon University Hospital (Besançon, France) and the French Research Ministry (AC-2015-2496, CNIL n°1173545, NF-S-138 96900 n°F2015).

#### ADDITIONAL INFORMATION

Bouezzedine F, **El Baba R**, Haidar Ahmad S, Herbein G. Polyploid Giant Cancer Cells Generated from Human Cytomegalovirus-Infected Prostate Epithelial Cells. *Cancers* 2023;15:4994. <https://doi.org/10.3390/cancers15204994>.

Prostate cancer remains a leading cause of death in men worldwide. Polyploid giant cancer cells (PGCCs) and chromosomal instability have been proposed to drive the progression of cancer. Given that HCMV infection has been implicated in malignant diseases from different cancer entities, in the present study, we assessed its transformation potential in vitro and evaluated the obtained cellular and molecular phenotypes of prostate epithelial cells (PECs) using HCMV high-risk clinical strains, DB and BL, which were previously isolated in our laboratory. HCMV-induced PGCC formation, Myc and EZH2 upregulation, as well as the stemness and epithelial–mesenchymal transition features verified the transformation process of PECs. Our research work deserves to be distributed among the scientific community, as it paves the way for upcoming studies targeting the potential role of HCMV and PGCCs in prostate cancer development and treatment.

**Simple Summary:** Prostate cancer remains a leading cause of death in men worldwide. Polyploid giant cancer cells (PGCCs) and chromosomal instability have been proposed to drive the progression of cancer. Given that HCMV infection has been implicated in malignant diseases from different cancer entities, in the present study, we assessed its transformation potential in vitro and evaluated the obtained cellular and molecular phenotypes of prostate epithelial cells (PECs) using HCMV high-risk clinical strains, DB and BL, which were previously isolated in our laboratory. HCMV-induced PGCC formation, Myc and EZH2 upregulation, as well as the stemness and epithelial–mesenchymal transition features verified the transformation process of PECs. Our research work deserves to be distributed among the scientific community, as it paves the way for upcoming studies targeting the potential role of HCMV and PGCCs in prostate cancer development and treatment.

**Abstract:** Background: Prostate cancer is the most commonly diagnosed malignancy and the sixth leading cause of cancer death in men worldwide. Chromosomal instability (CIN) and polyploid giant cancer cells (PGCCs) have been considered predominant hallmarks of cancer. Recent clinical studies have proven the association of CIN, aneuploidy, and PGCCs with poor prognosis of prostate cancer (PCa). Evidence of HCMV transforming potential might indicate that HCMV may be involved in PCa. Methods: Herein, we underline the role of the high-risk HCMV-DB and -BL clinical strains in transforming prostate epithelial cells and assess the molecular and cellular oncogenic processes associated with PCa. Results: Oncogenesis parallels a sustained growth of “*CMV-Transformed Prostate epithelial cells*” or CTP cells that highly express Myc and EZH2, forming soft agar colonies and displaying stemness as well as mesenchymal features, hence promoting EMT as well as PGCCs and a spheroid appearance. Conclusions: HCMV-induced Myc and EZH2 upregulation coupled with stemness and EMT traits in IE1-expressing CTP might highlight the potential role of HCMV in PCa development and encourage the use of anti-EZH2 and anti-HCMV in PCa treatment.

## 1. Introduction

Prostate cancer (PCa) is the most common solid tumor in men and the most prevalent tumor in the genitourinary system [1]. Based on the American Cancer Society’s statistics in 2022, PCa was considered the most frequent malignancy and the second-ranked cause of death among men in the United States [2,3]. Variable risk factors may influence the risk of developing PCa; however, little evidence exists for PCa prevention strategies except for early diagnosis, which aids in reducing PCa mortality [2,3]. In asymptomatic early stages, PCa, also called localized PCa, is not detectable. This explains the severity of PCa in terminal stages, indicating the presence of metastatic sites or a castration-resistant cancer

form (CRPC), which are often difficult to treat. At that stage, the median survival is 9 to 30 months [4].

Chromosomal instability, or CIN, has long been viewed as a topic of choice in cancer research [5] and a predominant hallmark of cancer [6]. Studying CIN can be beneficial for patient management involving diagnosis, prognosis, therapy, and genetic counseling [7]. A study showed that therapy monitoring using CIN led to the reduction of genome chaos-mediated drug resistance [5]. It is worth noting that CIN and aneuploidy are not identical, as aneuploidy represents a state of imbalanced karyotype [8]. In PCa, clinical studies revealed that CIN and aneuploidy have been linked to aggressive lethal disease [8,9], where castration and chemotherapy-resistant tumors showed a high incidence of CIN [9]. Polyploid giant cancer cells, or PGCCs, are formed through endoreplication and are considered a special subpopulation of cancer cells that contribute to solid tumor heterogeneity [10,11]. Recently, urinary PGCCs were detected in prostate cancer tissues [12]. Further, these giant cells contributed to the production of mononucleated aneuploid cells via neosis and might result in clinical relapse and chemoresistance in CRPC [13].

Prostate cancer pathogenesis involves heritable and environmental factors. A possible viral etiology of prostate cancer progression has been suggested, and evidence for viral-mediated genetic changes and associated immune dysregulation has been explored for many viruses, especially those known for infection of the anogenital and urinary sites [14]. HCMV, or human herpesvirus 5 (HHV-5), is a ubiquitous DNA virus that is detected in the urine and prostate tissue of infected subjects [15,16]. It infects between 40% and 95% of the population worldwide [17]. In healthy individuals, HCMV infection is considered mild or asymptomatic; however, in immunocompromised patients, it causes life-threatening illness in addition to congenital infections [18]. HCMV of prostatic origin established a long-term persistent infection in human embryo lung cells (HEL cells) *in vitro* [19]. Further, HCMV-specific intracellular immunofluorescent antigens were detected in prostatic cancer cell cultures [20,21]. An HCMV isolate that transformed HEL cells *in vitro* was yielded from normal human prostatic tissue [21]. Upon transplantation to athymic nude mice, these cell transformants were highly oncogenic [20]. These complex findings constitute further evidence of HCMV transforming capacity and indicate that HCMV may be involved in the development of prostatic neoplasia [20–22].

In agreement with the research findings of Rapp and Geder around fifty years ago, beyond the oncomodulation model, the presence of HCMV nucleic acid and proteins in several tumors (for instance, glioblastoma, neuroblastoma, colon cancer, breast cancer, and ovarian cancer) promoted HCMV as an oncovirus and highlighted a strong link between persistent HCMV infection and malignancy [23]. Recently, our group confirmed a potential direct oncogenic feature of HCMV and highlighted the role of polyploid giant cancer cells (PGCCs) in the HCMV-mediated transformation process, in agreement with the giant cell cycling theory unveiled recently by Liu and colleagues [24,25]. The oncogenic processes associated with HCMV infection at the cellular and molecular levels involved the transformation of epithelial cells, sustained proliferative signaling, growth suppressor evasion and apoptosis, and generation of PGCCs, as well as invasion and metastasis [26–28].

In line with the oncogenic potential of HCMV in mammary epithelial cells, we investigated its link with PCa. First, by revealing a direct transformation of prostate epithelial cells infected by the high-risk HCMV clinical strains (DB and BL HCMV strains) already isolated in our laboratory. Second, by exploring the molecular and cellular oncogenic processes associated with PCa cancer—for instance, generation of PGCCs, formation of soft agar colonies, and spheroid formation, as well as the induction of stemness and EMT markers.

## 2. Materials and Methods

**Cell cultures.** Human prostate epithelial cells (PECs) (Ref: CC-2555) were purchased from Lonza (Basel, Switzerland). The cells were maintained in prostate epithelial cell growth medium BulletKit (CC-3166) and were cultured under standard conditions (37 °C,

5% CO<sub>2</sub>, 95% humidity). Cultures were free of mycoplasma as determined by monthly screening (VenorGem classic mycoplasma detection, Minerva biolabs).

**Viral growth and PEC infection.** Clinical HCMV strains, namely HCMV-DB (GenBank KT959235), -BL (GenBank MW980585), -KM, and -FS, were isolated from patients who were hospitalized at Besançon University Hospital (Besançon, France) as previously described [26,29]. The human prostate epithelial cells were infected overnight with a multiplicity of infection (MOI) of 1. Screening of our viral stocks was conducted using real-time quantitative PCR to rule out the presence of other oncoviruses, namely EBV (sense, 5'-GATTTGGACCCGAAATCTGAT-3'; anti-sense, 5'-TCTGGGGGCTTATTCCTCTT-3') and HPV (HPV16(E6) sense, 5'-GCACAAAAGAGAAGTCAATGTT-3'; anti-sense, 5'-AGTCATATACCTCACGTCGAGTA-3'). PEC infections, quantification of HCMV replication, and HCMV detection were performed as previously described [26]. For HCMV quantification, supernatants from infected PECs were harvested, DNA was isolated (EZNA Blood DNA Kit, D3392-02, Omega BIO-TEK, Norcross, GA, USA) and real-time IE1 quantitative PCR (qPCR) was performed using a Stratagene Mx3005P thermocycler (Agilent Technologies, Santa Clara, CA, USA) and IE1 primers (sense, 5'-CGACGTTCTGCAGACTATG-3'; anti-sense, 5'-TCCTCGGTCACTTGTTCAAA-3'). qPCR was carried out using KAPA SYBR FAST Master Mix (KAPA BIOSYSTEMS, Potters Bar, UK). Results were collected and analyzed using MxPro qPCR software (Version 3.2).

**Microscopy.** Infected prostate cell cultures were monitored by an Olympus optical microscope (Olympus Corporation, Tokyo, Japan) and OPTIKA microscopy digital camera (Opticam, Romano d'Ezzelino, Italy). Confocal microscopy of prostate epithelial cells was performed as described previously [26]. Briefly, cells were washed with 1 × PBS, fixed and permeabilized (BD Cytfix/Cytoperm, 554722) and subsequently stained with the following antibodies: anti-IE1 (pp72), anti-Myc, anti-EZH2, anti-Nestin, anti-Nanog, anti-SOX2, anti-vimentin, and anti-E-cadherin. For visualization of the nucleus and the cytoplasm, DAPI (4', 6'-diamidino-2-phenylindole) and phalloidin staining, respectively, were performed according to the manufacturer's protocol. After staining, confocal imaging was performed using a 63 × oil immersion objective lens with an LSM800 Carl-Zeiss confocal microscope (Germany). Images were analyzed by using ZenBlue Software (Version 3.6, Carl-Zeiss Microscopy GmbH, Oberkochen, Germany). The antibodies used are provided in Supplementary Table S1.

**Flow cytometry analysis.**  $1 \times 10^5$  cells were collected from uninfected and infected PECs. Cells were fixed and permeabilized using 100 µL of BD Biosciences Cytfix/Cytoperm solution (554722) for 20 min at 4 °C and washed twice with 1 × BD Perm wash. Cells were then stained using the respective primary and secondary antibodies, as reported previously [26]. Cells were then subjected to cytofluorometric analysis using a BD LSRFortessa X-20 (BD Biosciences, Franklin Lakes, NJ, USA) flow cytometer. Data obtained were analyzed and processed using FACSDiva software (BD FACSDiva 8.0.1, BD Biosciences). The antibodies used are provided in Supplementary Table S1.

**Soft agar colony formation assay.** Colony formation in soft agar seeded with uninfected PECs and DB- and BL-infected PECs was assayed using Cell Biolabs Cytosolic Cell Transformation Assay Kit (Colorimetric assay, CB 135; Cell Biolabs Inc., San Diego, CA, USA) as per the manufacturer's protocol. Colonies were observed under an Olympus microscope (Olympus Corporation, Tokyo, Japan).

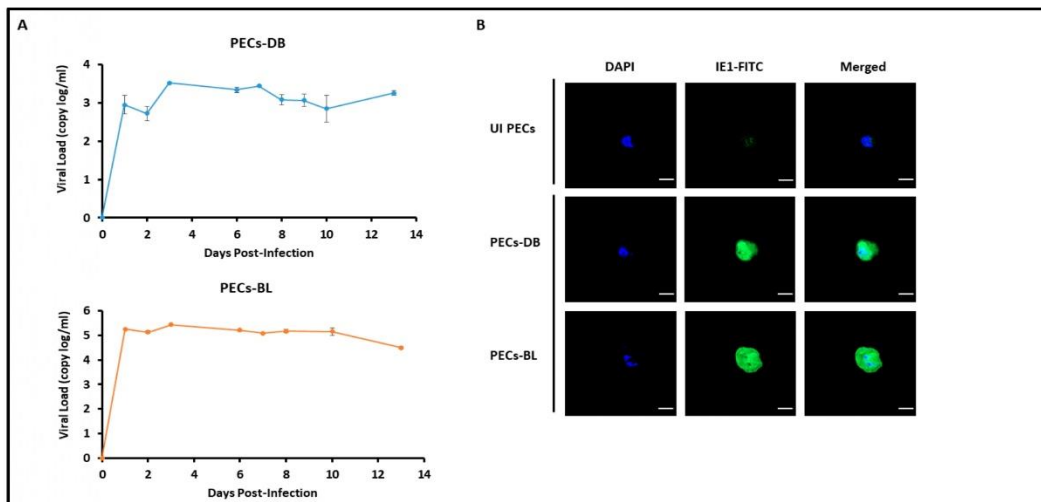

**Spheroid formation assay.** Spheroids of PECs were prepared as described previously [30]. Single cells ( $2 \times 10^3$ ) isolated using accutase were seeded in a serum-free PEC medium containing methylcellulose.

**Statistics.** Quantitative results are reported as mean ± SD of independent experiments. Statistical analyses were done using the Mann–Whitney test; a *p*-value ≤ 0.05 was considered to be statistically significant [\*; ≤0.05; \*\*; ≤0.01; \*\*\*; ≤0.001]. Microsoft Excel v2309 was used to construct the plots and histogram data.

### 3. Results

#### 3.1. HCMV-DB and -BL Clinical Strains Chronically Infected PECs Generating CTP Cells with PGCCs

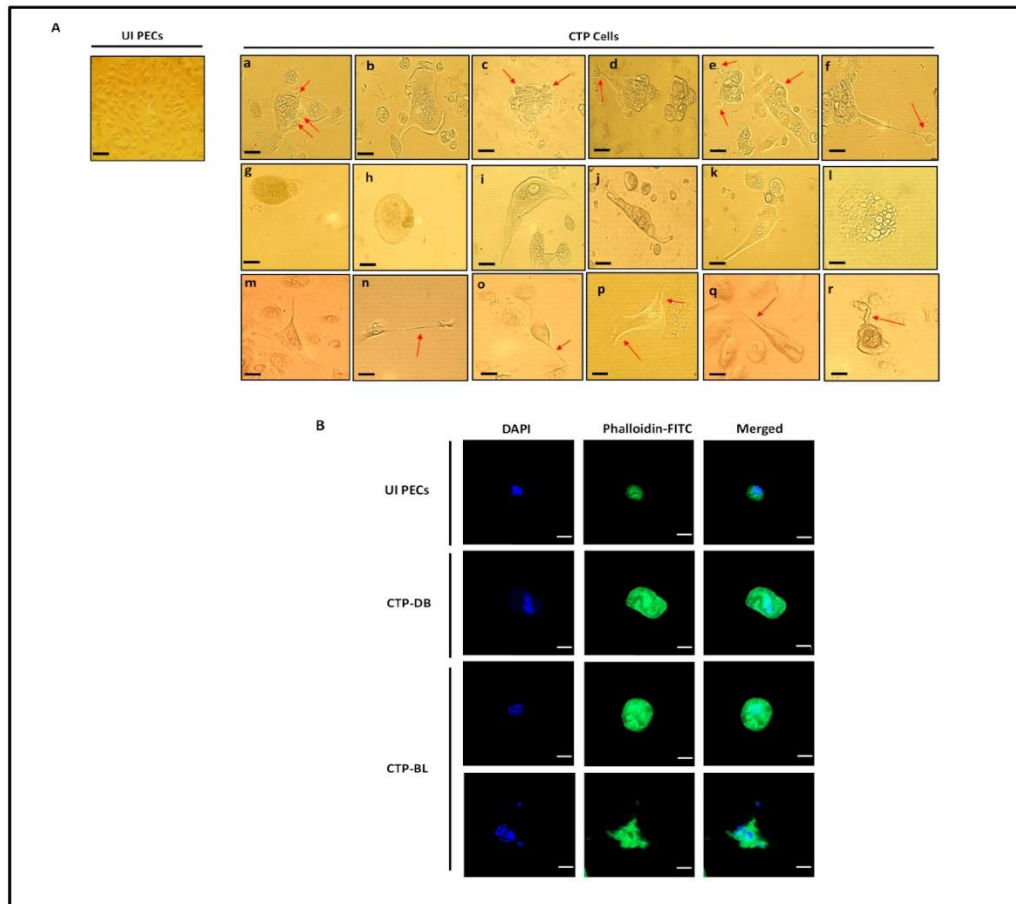

In PECs, all HCMV clinical strains replicated, showing a peak viral replication at days 3, 3, 13, and 9 post-infection with HCMV-DB, HCMV-BL, HCMV-KM, and HCMV-FS, respectively (Figure 1A and Supplementary Figure S1). The peak of HCMV load was 3 and 5 logs in PEC-DB and -BL, respectively (Figure 1A). HCMV-IE1 protein was detected in PEC-DB and -BL (Figure 1B). HCMV replication was further detected in the chronically infected PEC-DB and -BL cells (Supplementary Figure S2).

**Figure 1.** Replication of HCMV-DB and -BL strains in PEC cultures. (A) Time course of the viral titer in the supernatant of PECs infected with HCMV-DB and -BL as measured by IE1-qPCR. (B) Confocal microscopic images of IE1 staining in PEC-DB and -BL. UI PECs were used as controls; magnification  $\times 63$ , scale bar  $10 \mu\text{m}$ . Data are represented as mean  $\pm$  SD of two independent experiments.

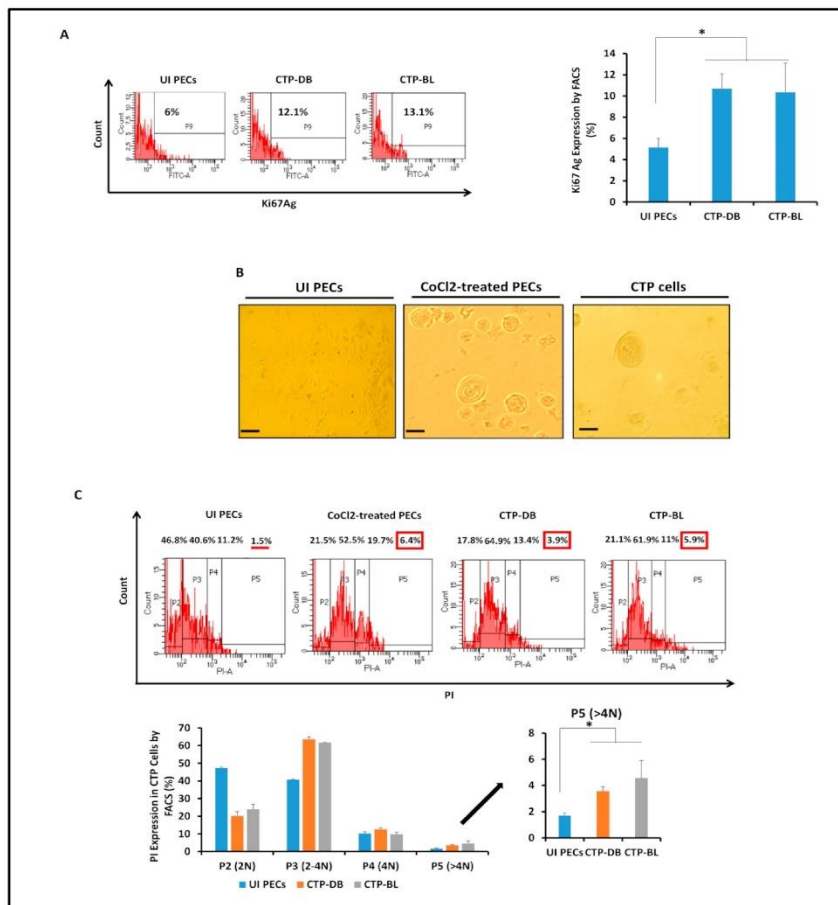

In chronically infected PEC cultures, we detected giant cells having large nuclei that were observed only in PECs chronically infected with the high-risk HCMV-DB and -BL strains, unlike uninfected PECs (Figure 2A) and PECs chronically infected with HCMV-KM and -FS strains. The emerging cells were termed “CMV-Transformed Prostate epithelial cells” or CTP cells, equivalent to the transformed cells that were previously reported by our group, namely, “CMV-Transformed Human mammary epithelial cells” or CTH cells, and “CMV-Elicited Glioblastoma Cells” or CEGBCs [28,29]. Cellular heterogeneity, including giant cells, blastomeres, blastocytes, multinucleated, budding, and mesenchymal cells, as well as cells showing filopodia and lipid droplets (Figure 2A), were detected in CTP-DB and -BL cultures. The presence of PGCCs and budding cells was confirmed by confocal staining of CTP cells (Figure 2B). On evaluating the proliferation potential of CTP cells, Ki67Ag was assessed in CTP cells; Ki67Ag expression was elevated in CTP-DB and -BL cells compared to uninfected PECs ( $p$ -value<sub>UIPECs;CTP-HCMV</sub> = 0.02) (Figure 3A). Further, polyploidy was detected mainly in CTP-DB and -BL cells compared to UI PECs; cobalt chloride ( $\text{CoCl}_2$ ) was used as a positive control to induce PGCC formation in PEC cultures (Figure 3B). CTP-DB and -BL cell populations were classified into PGCCs ( $>4$  N), large cells (4 N), intermediate cells (ICs of 2–4 N), and small cells (SCs of 2 N) (Figure 3C). The percentage of PGCCs was significantly increased in CTP-DB and -BL cultures ( $p$ -value

(UI PECs:CTP-HCMV) = 0.02). Increased polyploidy observed in CTP-DB and -BL cultures is in line with an almost two-fold increase in the S-phase (2–4 N) cells compared to uninfected PECs. Further, a drastic two-fold reduction was noticed in the 2 N cells of CTP-DB and -BL cultures compared to uninfected PECs (Figure 3C). Altogether, increased DNA synthesis and polyploidy were observed in CTP-DB and -BL cells compared to uninfected PECs.

**Figure 2.** Chronic infection of PECs with the high-risk HCMV strains and detection of morphological heterogeneity in CTP cultures. (A) Microscopic images of distinct cellular morphologies of the giant cell cycle, including (a–f) budding, (g,h) blastomeres and blastocytes, (i–k) mesenchymal cells, (l) lipid droplet-filled cells, (m–r) filopodia; magnification  $\times 100$ , scale bar  $100\ \mu\text{m}$  (for UI PECs) and  $\times 200$ , scale bar  $50\ \mu\text{m}$  (for images a–r). Uninfected PECs were used as a control. (B) Confocal microscopic images of DAPI and phalloidine staining in CTP-DB and -BL cells. Uninfected PECs were used as a negative control; magnification  $\times 63$ , scale bar  $10\ \mu\text{m}$ . Red arrows show the defined morphologies.

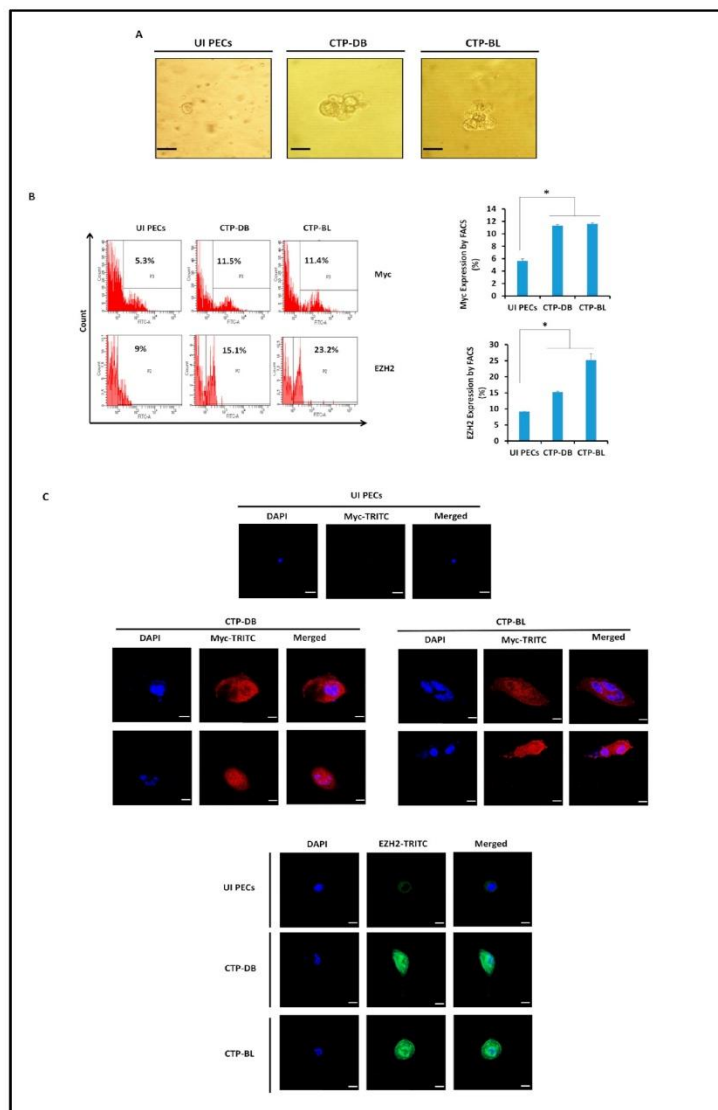

**Figure 3.** Assessing the proliferative potential and detecting polyploidy in CTP-DB and -BL cultures. (A) FACS staining of Ki67Ag in uninfected PECs as well as CTP-DB and -BL cells. (B) Microscopic images of polyploidy detected in CTP-DB and -BL cultures. Cobalt chloride (CoCl<sub>2</sub>)-treated PECs (300 μM) were used as a positive control, while uninfected PECs were used as a negative control. Magnification ×200, scale bar 50 μm. (C) Propidium iodide (PI) staining for polyploidy detection in CTP-DB and -BL cells by FACS. CoCl<sub>2</sub>-treated PECs were used as a positive control, and uninfected PECs were used as a negative control. Data are represented as mean ± SD of two independent experiments. \* *p*-value ≤ 0.05. The red line shows the low percentage of P5 (>4N). Red boxes emphasize the high percentages of p5 (>4N).

**3.2. CTP Cells Exhibited Dedifferentiation, Stemness, and EMT Traits Parallel to the Sustained HCMV Replication**

CTP-DB and -BL cells were seeded in soft agar to assess their oncogenic transforming potential. Colony formation was detected in the cultures seeded with CTP-DB and -BL cells compared to uninfected PECs (Figure 4A). EZH2 and Myc upregulation was detected in CTP-DB and -BL cells compared to uninfected PECs (*p*-value<sub>(UI PECs:CTP-HCMV)</sub> = 0.02)

(Figure 4B). In CTP cells, the elevated levels of EZH2 and Myc proteins were confirmed by confocal microscopy imaging (Figure 4C). Suz12 expression was decreased in CTP-DB and -BL cells compared to uninfected PECs ( $p$ -value (UI PECs:CTP-HCMV) = 0.02) (Supplementary Figure S3).

**Figure 4.** Transformation potential and phenotypic characterization of CTP-DB and -BL cells. (A) Colony formation in soft agar seeded with CTP-DB and -BL cells; uninfected PECs were used as a

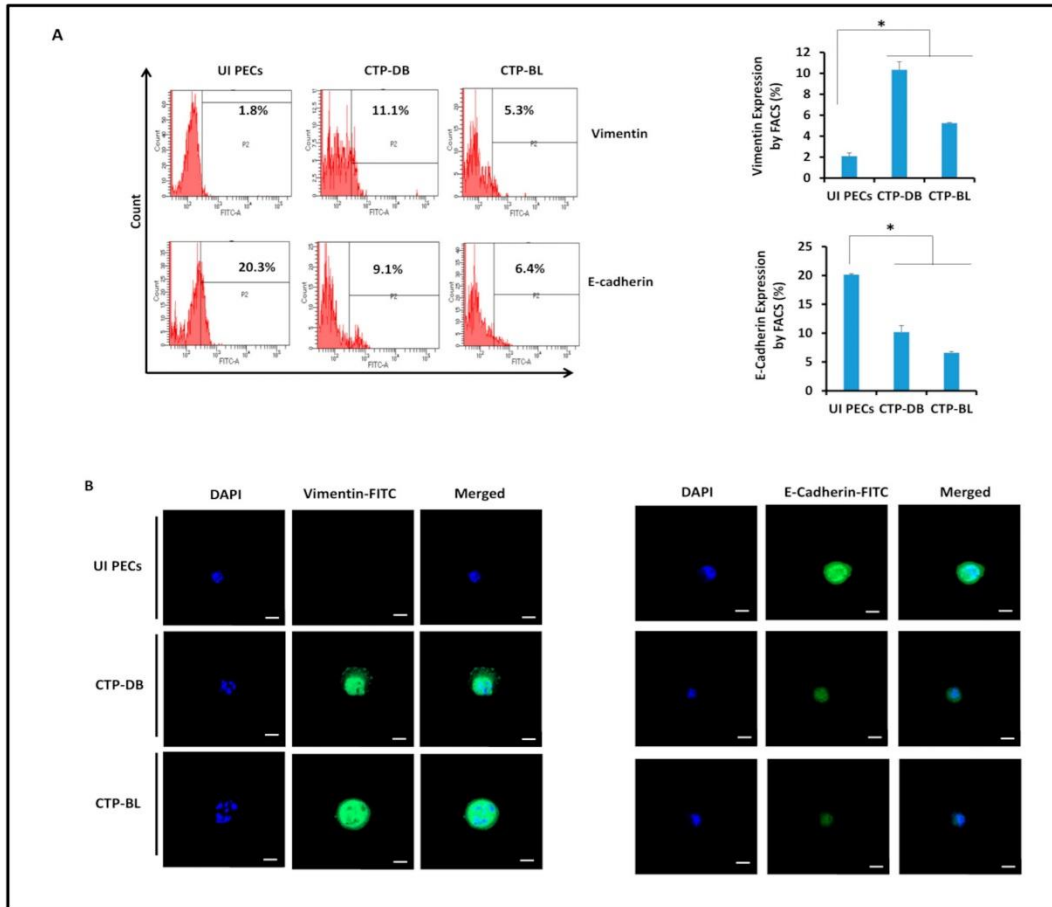

negative control. Formed colonies were observed under an inverted light microscope (magnification  $200\times$ , scale bar  $50\ \mu\text{m}$ ). (B) FACS staining of Myc and EZH2 in uninfected PECs as well as CTP-DB and -BL cells. Data are represented as mean  $\pm$  SD of two independent experiments. (C) Confocal microscopic images of Myc, EZH2, and DAPI staining in CTP-DB and -BL cells. Uninfected PECs were used as controls; magnification  $\times 63$ , scale bar  $10\ \mu\text{m}$ . \*  $p$ -value  $\leq 0.05$ .

In addition to PGCC presence in CTP cultures, spontaneous spheroids, as well as methylcellulose-induced spheroids, were detected in CTP-DB and -BL cultures (Figure 5A,B). Nestin, an intermediate filament protein and marker of undifferentiated cells [31], was upregulated in CTP-DB and -BL cultures compared to uninfected PECs (Figure 5C). Nanog and SOX2 expression in CTP-DB and -BL cells revealed an embryonic stemness phenotype within the aforementioned HCMV-transformed cells (Figure 5C).

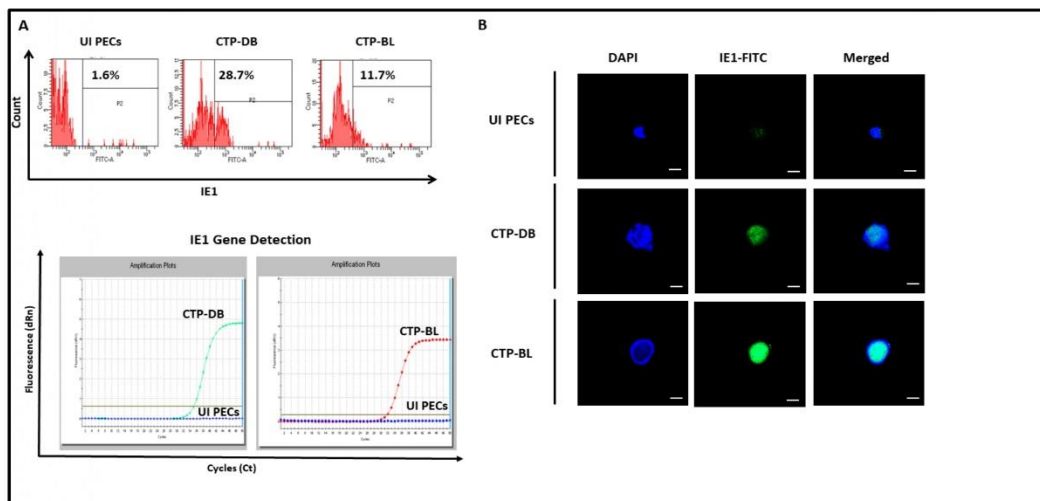

**Figure 5.** CTP-DB and -BL cells display a stemness phenotype. (A) Spontaneous spheroids were detected under an inverted light microscope in CTP-DB and -BL cultures. Magnification  $\times 200$ , scale bar  $50\ \mu\text{m}$ . (B) Spheroids were observed in the chronically infected CTP-DB and -BL cell cultures in methylcellulose, scale bar  $25\ \mu\text{m}$ . (C) Confocal microscopic images of Nestin, Nanog, SOX2, and DAPI staining in CTP-DB and -BL cells. Uninfected PECs were used as controls; magnification  $\times 63$ , scale bar  $10\ \mu\text{m}$ .

Through EMT, tumors can attain a mesenchymal phenotype close to cancer stem cell features that contribute to metastasis [32]. Vimentin expression was upregulated in CTP-DB and -BL cultures ( $p$ -value<sub>UI PECs:CTP-HCMV</sub> = 0.02), whereas E-cadherin was downregulated compared to uninfected PECs ( $p$ -value<sub>UI PECs:CTP-HCMV</sub> = 0.02) (Figure 6A,B).

**Figure 6.** EMT in CTP-DB and -BL cultures. (A) Vimentin and E-cadherin expression by FACS in CTP-DB and -BL cells. Uninfected PECs were used as controls. Data are represented as mean  $\pm$  SD of two independent experiments. (B) Confocal microscopic images of vimentin, E-cadherin, and DAPI staining in CTP-DB and -BL cells. Uninfected PECs were used as controls; magnification  $\times 63$ , scale bar 10  $\mu$ m. \*  $p$ -value  $\leq 0.05$ .

In PECs chronically infected with high-risk HCMV-DB and -BL, HCMV replication was sustained (Figure 7). IE1 protein and gene were remarkably detected in CTP-DB and -BL cells versus uninfected PECs (Figure 7A,B).

**Figure 7.** Sustained HCMV replication in CTP-DB and -BL cultures. (A) IE1 protein and gene expression in chronically infected CTP-DB and -BL cell cultures by FACS and qPCR, respectively. Uninfected PECs were used as a negative control. (B) Confocal microscopic images of IE1 and DAPI staining in CTP-DB and -BL cells. Uninfected PECs were used as controls; magnification  $\times 63$ , scale bar  $10 \mu\text{m}$ .

#### 4. Discussion

Polyploidy, a feature of chromosomal instability, can be triggered by oncoviruses [33]. In our study, we evaluated the transforming capacities of the high-risk oncogenic HCMV-DB and -BL strains following PEC infection. An oncogenic environment, along with a sustained growth of CTP cells with soft agar colonies, was detected upon infecting PECs with HCMV-DB and -BL. The HCMV-transformed PECs or CTP cells dedifferentiated, displayed stemness traits, gained mesenchymal features promoting EMT, and yielded PGCCs (Figure 8 and Supplementary Figure S4), and they also possessed spheroid formation potential. HCMV detection, PGCC appearance, and Myc and EZH2 upregulation verified the transformation process in PECs.

CIN/aneuploidy is associated with tumor progression and is considered a poor prognostic biomarker in various tumor types, including prostate cancer [8,9]. Knowing that the exerted potential oncomodulatory effects of HCMV infection are through enhanced replication stress, subverted DNA damage response, and induced genomic instability [34], it is of high importance to maintain CIN/aneuploidy under a tolerable threshold; this is to prevent tumor aggressiveness [7,9]. PGCC presence has been described in multiple tumors—for instance, breast, ovarian, colon, melanoma, lung, pancreas, urinary bladder, renal, thyroid, and prostate [24,26,35,36]. Studies with human prostate cancer cell lines showed that PGCCs are more aggressive, metastatic, and highly resistant to common chemotherapies [25,37]. They constitute stem cell-like traits and express various embryonic stem cell markers facilitating cancer cell survival, therapy resistance, and tumor relapse [36,37]. In line with the previous studies, CTP cells showed various cellular morphologies, including multinucleated cells, cell budding, blastomeres, blastocytes, filopodia, and cells with lipid droplets. The aforementioned morphologies were previously detected in PCa [36,38–40]. In agreement with the blastomere-like stemness and giant cell life cycle reported previously by Niu et al. [41,42], we observed the PGCC appearance as well as cellular heterogeneity in HCMV-transformed prostate epithelial cell cultures (CTP cells). The CTP cell popula-

tion was highly heterogeneous, including PGCCs, blastomere-like cells, morula-like cells, mesenchymal cells, and small cells. The described patterns could be representative of self-renewing cells undergoing diverse stages of the previously described giant cell cycle. Thus, our outcomes revealed that PGCCs harboring HCMV might promote a malignant phenotype via giant cell cycling [24,25].

**Figure 8.** A schematic diagram illustrating giant cell cycling in CTP-DB and -BL cultures. Microscopic images of distinct cellular morphologies of the giant cell cycle; magnification  $\times 200$ , scale bar  $50\ \mu\text{m}$  (initiation, self-renewal, and termination phases), and  $\times 100$ , scale bar  $100\ \mu\text{m}$  (stability phase). Initiation, self-renewal, termination, and stability represent the four different stages of the giant cell cycle. Post-HCMV infection and via endoreplication, the  $2\ \text{N}$  PECs go into the initiation phase. Subsequently, polyploid cells ( $>4\ \text{N}$ ) and tetraploid cells ( $4\ \text{N}$ ) are produced in the self-renewal/dedifferentiation phase. During the termination/differentiation stage, the intermediate cells ( $2\text{--}4\ \text{N}$ ) will be generated from multinucleated or mononucleated giant cells through budding. Intermediate PECs enter the stability stage and are afterward replaced by diploid small PECs ( $2\ \text{N}$ ).

In addition to PGCCs, numerous other cellular and molecular mechanisms could account for the genome chaos observed in various solid tumor types, including, among others, chromothripsis [43], drug-tolerant persister (DTP) cancer cells [44], reversible senescence [45], treacherous apoptosis [46], oncogenic p21WAF1 expression [47,48], and anastasis [49]. Although we identified here the role of HCMV in PGCC formation, we cannot

exclude the role of HCMV in the appearance of other aspects of genome chaos. HCMV induces the generation of intracellular reactive oxygen intermediates (ROIs) within minutes after infection of the cell, and then it uses these ROIs to facilitate its own gene expression and replication. Conversely, antioxidants inhibit HCMV immediate early gene expression and viral replication [50]. Since there is an increasing consensus that disrupting redox homeostasis by intervening with redox signaling is theoretically a promising therapeutic strategy for targeting drug-tolerant persister cancer cells [51], it might be possible that HCMV will modulate redox signaling in infected cells and, thereby, play a role in the generation/maintenance of DTP cancer cells. Programmed cell death or apoptosis has generally been viewed as a protective mechanism that suppresses tumor growth and prevents tumor progression. However, recent studies have shown that apoptosis can also have a paradoxical pro-tumoral role by increasing genomic instability, creating an immunosuppressive microenvironment, or driving therapy resistance. Thus, recently, it has been shown that islands of apoptotic cell death are strongly associated with tumor heterogeneity in their special proximity *in vivo* and induce therapy resistance *in vitro*. Since apoptosis disorder is a key pathogenesis mechanism of HCMV-related diseases [52], we cannot exclude that HCMV infection could be involved in the foci of apoptotic cells, thereby leading to tumor heterogeneity/therapy resistance.

Recent advances in genomics and proteomics highlighted the essential role of certain biomarkers in several tumors, mainly PCa [53,54]. Myc overexpression contributed to prostate tumor initiation and progression by disrupting transcriptional pause release at androgen receptor-regulated genes [55]. Other studies highlighted the oncogenic function of the methyltransferase EZH2 in castration-resistant prostate cancer cells, where EZH2 acts as a coactivator for critical transcription factors, including the androgen receptor [56,57]. In line with the previously mentioned findings, Myc and EZH2 overexpression was detected in CTP-DB and -BL cells compared to uninfected PECs. The CTP stemness phenotype was confirmed by the spheroids detected in CTP-DB and -BL cultures in addition to the high expression of nestin, Nanog, and SOX2, which are shown to be linked to prostate cancer development, progression, invasion, and metastasis [31,58–60]. Prostate cancer cells acquire invasive and metastatic characteristics via EMT [61,62]. Increasing evidence indicates that EMT promotes prostate cancer metastatic progression, and it is mainly associated with increased stemness and drug resistance [63]. In our study, vimentin was highly expressed in CTP cells, unlike E-cadherin, which was downregulated in CTP-DB and -BL cells, in line with the EMT phenotype.

Several studies have revealed the presence of infectious agents in the prostate, including oncogenic viruses, such as HPV, EBV, and BK polyomavirus [64,65]. The strength of the viral etiology and the molecular events involved in the development of PCa are still unclear. Recent evidence concluded that the HPV high-risk types have a causal role in prostate cancer [66]. HPV oncogenic proteins (E6 and E7) exert their carcinogenic potential through interacting with and degrading tumor suppressors (p53 and Rb) [67]. The association between EBV and prostate cancer is still under debate [68]. Although herpes simplex virus (HSV) is not recognized as an oncovirus, a significant association between prostate cancer and serologic evidence of HSV-2 infection is probably due to a long latency period for prostate cancer progression after HSV-2 infection [69].

Infecting PECs with the high-risk HCMV strains, namely DB and BL, revealed a sustained viral replication through the detection of HCMV-IE1 in chronically infected cultures, suggesting that HCMV infection could potentially promote cancer progression. We believe that there is an alternation of productive and latent phases in the HCMV-transformed cells, as already reported for other herpes oncoviruses, namely KSHV and EBV [70,71].

In agreement with our results, several studies showed that HCMV may be directly involved in the development of prostatic intraepithelial neoplasia [16,22]. Nevertheless, the association between HCMV and PCa has been explored, in which two out of ten case-control studies revealed no significant association between HCMV and increased PCa

risk [66,72–78]. In fact, the observed discrepancies between these studies at the molecular and serological level may depend on the differences in techniques' sensitivity for detecting HCMV in prostate tissues. In addition to its direct oncogenic potential, an oncomodulatory effect of HCMV linked to the ability of HCMV to interfere with the transforming cell properties has been reported [79,80]. A study done by Blaheta et al. on the prostate cancer cell model (PC3) demonstrated that HCMV acts on the invasive properties of the prostatic cancerous cell line PC3, and this carcinogenic process is promoted by elevated c-Myc levels [81]. Also, androgen in the prostate could activate the HCMV major immediate early promoter (MIEP), leading to viral replication, which might contribute to oncomodulation in prostate cancers [82].

## 5. Conclusions

In conclusion, HCMV-induced Myc and EZH2 overexpression, along with the stemness and EMT cellular phenotypes in IE1-expressing PECs, led to the appearance of transformed CTP cells and might determine a significant model in the context of PCa. Furthermore, the use of anti-EZH2 and anti-HCMV therapies could open the door to new avenues that might be beneficial in the management of PCa, especially the more aggressive castration-resistant ones, such as hormone-refractory PCa with high metastatic potential.
