## Abstract

How can we reconfigure a given set of $n$ segments with fixed endpoints in the plane into a crossing-free set? We remove a pair of crossing segments and insert one of the two pairs of non-crossing segments with the same four endpoints in an operation called a flip. If we restrict ourselves to sets of segments with a given property, say forming one polygon, the inserted pair must preserve this property. Untangling a set of segments amounts to iteratively flip the set of segments until no crossing remains.

Why are flips useful? A flip shortens the total length of the segments. Hence, to efficiently compute approximations of the shortest tour through $n$ given cities, many well known algorithms are supplemented with flips.

How many flips are needed? At most $n^{3}$ flips may be performed in a sequence, but the longest sequence known uses only roughly $n^{2}$ flips. In general, no strategy for choosing which pairs of crossing segments to remove is known to untangle a set of segments using fewer than $n^{3}$ flips. Yet, when the endpoints form a convex polygon, the problem is well understood: the longest sequences use roughly $n^{2}$ flips, while the best strategies use roughly $n$ flips.

In this dissertation, we devise strategies to untangle segments for several versions of flips: the flips with nothing to preserve (the segments form a multigraph or a matching), the flips preserving a bipartite matching, the flips preserving a polygon (i.e., a tour), and the flips preserving a tree. We study the performance of each strategy in terms of their number of flips. Our results are organized by the type of choice the strategy uses, as follows. We first study the performance of the strategy choosing nothing, i.e., we improve the bounds on the number of flips in the longest flip sequences (in special cases). We then devise strategies for choosing which pairs of segments to remove to untangle segments using as few flips as possible. We also devise strategies for choosing which pairs of segments to insert, and strategies for choosing both removed and inserted pairs. Many of our results use a parameter measuring how far from a convex polygon the set of endpoints is. Furthermore, we prove the $\mathcal{N} \mathcal{P}$-hardness of the shortest flip sequence to untangle a bipartite matching.

## Résumé

Comment reconfigurer $n$ segments avec un ensemble fixé d'extrémités pour qu'ils ne se croisent pas? Nommons décroisement l'opération qui consiste à retirer une paire de segments qui se croisent pour en insérer une autre parmi les deux paires de segments non croisés partageant les mêmes quatre extrémités. Si nous nous restreignons à des ensembles de segments ayant une propriété donnée, à des polygones par exemple, l'insertion de la paire doit préserver cette propriété. Décroiser totalement un ensemble de segments consiste à itérer les décroisements jusqu'à ce qu'il ne reste plus de croisement.

À quoi sert de décroiser des segments? Un décroisement raccourcit la longueur totale des segments. Pour calculer efficacement des approximations du plus court trajet passant par $n$ villes données et revenant à son point de départ, de nombreux algorithmes bien connus font recours à des décroisements pour cette vertu.

Combien de décroisements sont nécessaires pour un décroisement total? Un décroisement total est toujours atteint en au plus $n^{3}$ décroisements, pourtant, la plus longue séquence connue ne comporte qu'environ $n^{2}$ décroisements. En général, nous ne savons pas comment choisir stratégiquement quelles paires de segments retirer pour décroiser totalement les ensembles de segments en utilisant moins de $n^{3}$ décroisements. Le problème est cependant bien compris lorsque les extrémités des segments forment un polygone convexe : les séquences les plus longues comportent environ $n^{2}$ décroisements, tandis que les meilleures stratégies utilisent environ $n$ décroisements.

Dans cette thèse, nous élaborons des stratégies pour décroiser totalement des segments, et ce pour plusieurs versions de décroisements : les décroisements n'ayant rien à préserver (les segments forment par exemple un multigraphe ou un couplage), les décroisements préservant un couplage bipartite, les décroisements préservant un polygone (c'est-à-dire un trajet revenant à son point de départ), et les décroisements préservant un arbre. Nous étudions les performances de chaque stratégie en termes de nombre de décroisements utilisés. Nos résultats sont organisés suivant le type de choix autorisé pour les stratégies. Nous étudions d'abord les performances de la stratégie qui ne choisit rien, c'est-à-dire que nous améliorons les bornes connues sur le nombre de décroisements dans les séquences de décroisements les plus longues (dans certains cas particuliers). Nous élaborons ensuite des stratégies pour choisir les paires de segments à retirer pour décroiser totalement des segments en utilisant le moins de décroisements possible. Nous élaborons également des stratégies pour choisir les paires de segments à insérer, ainsi que des stratégies pour choisir à la fois les paires à retirer et les paires à insérer. Beaucoup de nos résultats utilisent un paramètre mesurant à quel point l'ensemble des extrémités des segments est proche d'un polygone convexe. D'autre part, nous prouvons qu'il est $\mathcal{N} \mathcal{P}$-dur de calculer la plus courte séquence de décroisements pour décroiser totalement un couplage bipartite donné.

## Chapter 1

## Introduction

Motivation. Imagine ${ }^{1}$ that we have to visit $n$ given cities and come back to the city we first visited (Figure 1.1(a) shows $n=5$ cities and the roads between). Assuming

(a)

(b)

(c)

(e)

Figure 1.1: (a) Five cities and the roads between. (b) The shortest tour (of 125.6 km ). (c) A tour (of 159.3 km ) with a crossing. (d) The tour (of 136.2 km ) after a flip. (e) In the highlighted triangle, the dashed segment is shorter than the path formed by the two plain segments. The same holds in the other triangle, thus a flip shortens the tour.
that there is a flat and straight road between any two cities, what tour should we choose to minimize our total travel distance? This is perhaps the most natural version of the famous Traveling Salesperson Problem (TSP). Computing the exact shortest tour may require an exponential time, ${ }^{2}$ which is not practical for several applications (Figure 1.1(b) shows the shortest tour on five cities). To still compute a short tour when the exact shortest tour is not affordable, many powerful heuristics and approximation algorithms have been developed (see for example [9, 34, 51]). Many of them might produce self-intersecting tours like the tour in Figure 1.1(c). ${ }^{3}$ Yet, a self-intersecting tour is not optimal as it can be reconfigured into a shorter tour by replacing a pair of crossing segments by a non-crossing pair in an operation called a flip (a flip reconfigures the tour in Figure 1.1(c) into the tour in Figure 1.1(d) which is shorter as shown in Figure 1.1(e)). This folklore theorem, "Perhaps the oldest theorem concerning the TSP" [29], holds if the cities are not all colinear [82]. If general position is assumed,

[^0]applying the triangle inequality in the two triangles formed by the removed and inserted segments is enough (Figure 1.1(e)).

A reconfiguration problem. This flip operation falls in the range of reconfiguration problems, where some typical questions are "Is it possible to reconfigure a chair into a stool while preserving the fact that we can sit on it at every reconfiguration step?" and "What are the minimum number and maximum number of reconfiguration steps if the chair and the stool are chosen to be as different as possible?". We present some related reconfiguration problems in Section 1.4.

Figure 1.2: The valid insertion choice(s) to preserve (a) nothing special, (b) nothing special (but each point is the end point of exactly one segment), (c) segments with one red endpoint and one blue endpoint, (d) one tour (e) one tree. Small black discs are points, solid squares are red points and hollow circles are blue points, removed and inserted segments are bold (to be inserted segments are dashed in other figures).

From tours to segments. Flips are not specific to tours: a flip may apply to any set $^{4}$ of $n$ segments in the plane. In fact, all the results known for tours are essentially more general. In this generalized setting, performing a flip involves choosing which pair of crossing segments to remove and which of the two pairs of non-crossing segments with the same four endpoints to insert. When flipping a set of segments that has some property, for instance the property of being a tour, we additionally require the resulting set of segments to preserve this property (the same way we required each reconfiguration step of a chair to preserve the property of holding a sitting person). This requirement may impose which of the two possible pairs of non-crossing segments to insert (Figure 1.2(a) shows the two possible insertion choice in an arbitrary (multi)set of segments, Figure 1.2(b) shows the two possible insertion choice in a matching, i.e., a set of segments where each point is the endpoint of exactly one segment, Figure 1.2(c) shows the only insertion choice to preserve a bipartite matching, i.e., a matching where each segment has one red endpoint and one blue endpoint, Figure 1.2(c) shows the only insertion choice to preserve a tour, i.e., a polygon, Figure $1.2(\mathrm{~d})$ shows the only

[^1]insertion choice to preserve a tree, i.e., a set of roads connecting all the cities but with no cycle). Using the same example of tours, note that one of the two pairs of non-crossing segments with the same four endpoints would transform the tour into two tours, which is not wanted. We therefore insert the other pair in order to preserve the property of being one tour (Figure 1.2(d)).

Untangling segments. A flip may counter-intuitively increase (or leave unchanged) the total number of crossings; this occurs when some segments of our set cross one of the inserted segments without crossing any of the removed segments (the smallest horizontal segment in Figure 1.2). It is thus unclear whether performing flips as long as there remain crossings eventually terminates. To show that such a process terminates nonetheless with a set of crossing-free segments using at most an exponential number of flips, recall that each flip shortens the total length of the segments (Figure 1.1(e)). It therefore impossible to reach twice the same set of segments in the process. As there is an exponential number of ways $n$ segments can connect the same set of endpoints (Figure 1.3), the claim holds. This untangling process is used in practice to supplement heuristics and approximation algorithms for the TSP. Untangling is the only known way to get a crossing-free tour shorter than the initial tour in polynomial time [82]. In some situation a crossing-free solution is necessary [22].

Figure 1.3: All the $\frac{(n-1)!}{2}=12$ possible tours on the $n=5$ cities of Figure 1.1(a) sorted by decreasing length. A flip shortens a tour, thus a flip always moves forward in this list.

A historical bound. In 1980, Jan van Leeuwen and Anneke A. Schoone showed that untangling segments uses at most $n^{3}$ flips [82], ${ }^{5}$ which is much less than an exponential number. This $n^{3}$ upper bound is still the state of the art, yet the longest untangling process known only uses roughly $n^{2}$ flips $^{6}$ which corresponds to the maximum number of crossings in a set of $n$ segments. It is even more surprising that, in general, no strategy guiding the removal choices is known to use fewer flips than $n^{3}$ when no set of segments is known to require more than roughly $n$ flips to be untangled, leaving an even wider gap.

Nevertheless, these two gap problems are solved in the very special case where the

[^2]endpoints of the segments (the cities, in the TSP context) form a convex polygon: ${ }^{7}$ the longest untangling process uses roughly $n^{2}$ flips $^{8}$ and the best removal strategy uses roughly $n$ flips. Whether these two bounds also hold for general point sets is an open conjecture (the conjecture that the longest untangling process for matchings uses $\Theta\left(n^{2}\right)$ flips appears in [19]) from which stems the following problematic.

### 1.1 Problematic

The problematic of this dissertation is to devise strategies (for various choices) to untangle segments (while preserving various properties) and to establish their performance (mostly in terms of number of flips).

### 1.2 Contribution

In this section, we present the contributions of this dissertation. These contributions appear in $[30,31,32,33]$ (except Theorem 5.3.1). We start by explaining a notation that we use extensively to present the results. This notation is defined more formally in Chapter 2.

The unknown of this dissertation. Let d denote the performance of the optimal strategy, i.e., the worst case flip complexity of the problem of untangling segments; it is the unknown of this dissertation. To specify the choice the optimal strategy has, we use symbols in the exponent, as explained in the following.

- In $\mathbf{d}^{\emptyset}$, the optimal strategy has no choice at all, it amounts to choose nothing. The quantity $\mathbf{d}^{\varnothing}$ is thus the maximum number of flips used in an untangling process, and the state of the art is $n^{2} \preccurlyeq \mathbf{d}^{\emptyset} \preccurlyeq n^{3}$ as we have seen in a previous paragraph. ${ }^{9}$
- In $\mathbf{d}^{\mathrm{R}}$, the optimal strategy is a strategy for all the removal choices. The state of the art is $n \preccurlyeq \mathbf{d}^{\mathrm{R}} \preccurlyeq n^{3}$ as we have seen.
- In $\mathbf{d}^{\mathrm{I}}$, the optimal strategy is a strategy for all the insertion choices.
- In $\mathbf{d}^{\mathrm{RI}}$, the optimal strategy is a strategy for both removal and insertion choices.

We additionally specify the property to be preserve by the flips in the index. For example, in $\mathbf{d}_{\text {Cycle }}^{\mathrm{R}}$, all the sets of segments considered form a cycle (i.e., a tour) and all the flips considered preserve this property. The extensive list of the properties considered in this dissertation is in Chapter 2. We classify these properties into the following three types, and we often combine them.

[^3]1. The point set properties are the properties about the position of the endpoints that are preserved by any insertion choice at every flip such as Convex where the endpoints form a convex polygon (Figure 1.4(a)). We also consider seven different relaxations of this Convex property (Figure 1.4(b)-(h), (k)).
2. The insertion properties are the properties that impose which pair is inserted at every ${ }^{10}$ flip. We consider three such properties: Bipartite where the endpoints are colored red or blue and the segments must match a red point to a blue point (Figure 1.2(c)), Cycle where the segments form a tour (Figure 1.2(d)), and Tree where the segments form a tree (Figure 1.2(e)). We use Multigraph to explicitly say that the insertion choice is not impose by a property (Figure 1.2(a)).
3. The degree properties are the properties about the segments that are preserved by any insertion choice at every flip. In other words, a degree property is a set of constraints on the degree of each point. We consider only one such property: Matching where each endpoint is matched (via a segment) to exactly one other endpoint (Figure 1.2(b) show flips on a matching).

### 1.2.1 Upper Bounds

Note that devising a new strategy to untangle segments and measuring its performance upper bounds the corresponding version of $\mathbf{d}$.

Red-on-a-line point sets. The version of the problem where half of the points are red and lie on a line while the other half is blue and lie on a parallel line, and where a segment must match a red point to a blue point (the Bipartite Matching version) is fully solved as a set of segments is essentially a drawing of a permutation (Figure 1.4(1)) where crossings correspond to inversions, flips to inversion swaps, and untangling to sorting. An intermediate setting where all the red points lie on the same horizontal line and where all the blue points lie above this line (the Redonaline version, Figure 1.4(k)) has been studied in [17]. The following two results prolong this study.

In Theorem 4.4.1 [33], we prove that

$$
\mathbf{d}_{\text {Redonal ine Matching }}^{\emptyset}(n) \leq \frac{n(n-1)}{2} \frac{n+4}{6} \preccurlyeq n^{3},
$$

which only betters the state of the art general historic $n^{3}$ upper bound [82] by a factor $\frac{1}{6}$. We purposely factor the bounds by $\frac{n(n-1)}{2}=\binom{n}{2}$, the number of pairs of segments, as this quantity is closely related to the problem. The potential involved in this proof takes advantage of the connections bipartite matchings and permutations, and significantly differs form the potential used to prove the $n^{3}$ upper bound.

In Theorem 5.8.1 [33], we provide a simple removal strategy proving that

$$
\mathbf{d}_{\text {Redonaline Matching }}^{\mathrm{R}}(n) \leq \frac{n(n-1)}{2} \preccurlyeq n^{2} .
$$

[^4]

Figure 1.4: The different types of point sets considered in this dissertation. In the nine first figures, the point set $P$ is partitioned into $P=C \cup T$ with $C$ forming a convex polygon (shaded) and the points of $T$ (highlighted) positioned in various ways.
(a) A point set $P=C$ forming a convex polygon (i.e., satisfying the Convex property).
(b) \& (c) A point set with only one point in $T$ (i.e., satisfying the $|T|=1$ property).
(d) A point set with two points in $T$ both lying inside $C$ (i.e., satisfying the Inin property).
(e) A point set with two points in $T$ both lying outside $C$ (i.e., satisfying the Outout property).
(f) A point set with two points in $T$, one inside and one outside $C$ (i.e., satisfying the Inout property).
(g) A point set where the points of $T$ are separated from $C$ by two parallel lines (i.e., satisfying the Separated property).
(h) A point set where the points of $T$ all lie outside $C$ (i.e., satisfying the Allout property).
(i) \& (j) A general point set (in (i), the point set is viewed as a $P=C \cup T)$.
(k) A point set with $n$ red points (solid squares) on a line and $n$ blue points (hollow circles) above the line (i.e., satisfying the Redonaline property).
(l) A point set with $n$ red points on a line and $n$ blue points on a parallel line (i.e., satisfying the Permutation property).

This bound is only slightly better than the one in [17], but the removal strategy is simpler and, most importantly, the proof introduces a new approach called state tracking which sheds a new light on the untangling problem in general. For instance, state tracking provides a new level of understanding for Theorem 3.2.2 [17] and Theorem 4.2.1 [33].

Convex position point sets. The case where the endpoints of the segments form a convex polygon (Figure 1.4(a)) has a very rigid structure: the geometry of such a convex position is fully encoded in the cyclic order in which the points appear on the convex polygon. This convex case is thus well understood through a collection bounds, most of which are tight, in the literature. The following three results add to this collection.

In Theorem 5.2.1 [31], we use removal choice and the notion of crossing depth of a segment to prove that any $n$ segments with endpoints $C$ forming a convex polygon may
be untangled with roughly $n \log n$ flips. Stated as an upper bound, we have ${ }^{11}$

$$
\mathbf{d}_{\text {Convex Multigraph }}^{\mathrm{R}}(n) \preccurlyeq n \log |C| \preccurlyeq n \log n .
$$

This bound was already known for $n$ segments forming a tree [17]; this new proof is both simpler and more general.

In Theorem 5.3.1, we use removal choice and the notion of crossing depth again to prove that

$$
\mathbf{d}_{\text {Convex Tree }}^{\mathrm{R}}(n) \leq 3 n-8 \preccurlyeq n \quad \text { for } n \geq 3,
$$

thereby improving the aforementioned $n \log n$ upper bound [17].
In Theorem 6.1.1 [31], we use insertion choice to prove that

$$
\mathbf{d}_{\text {Convex Multigraph }}^{\mathrm{I}}(n) \preccurlyeq n \log |P| \preccurlyeq n \log n .
$$

The proof relies on a multiplicative potential instead of a classic additive potential. This bound improves on the general quadratic upper bound concerning insertion choice [19].

Near convex position point sets. As mentioned, endpoints forming a convex polygon admit a special treatment, but so far no work has been done to take advantage of situations where almost all the endpoints of the segments form a convex polygon (Figure 1.4(b)-(i)). The following eight upper bounds address this situation using the same notations described next. The set of endpoints is denoted $P$ and is partitioned into two subsets: the subset $C$ forming a convex polygon and the subset $T$ of all the remaining endpoints. We introduce the parameter $t$ defined as the number of segments which have at least an endpoint in $T$, counting twice a segment having its two endpoints in $T$. This parameter $t$ is a measure of how "far" the point set $P$ is from being in convex position with $C$. The proofs often involve a preprocessing of the segments whose endpoints are both in $C$ invoking one of the corresponding theorems for convex position. The proofs also involve splitting the segments to untangle them separately (see Lemma 2.6.1 [19, 31]).

In Theorem 4.3.1 [30], we prove that

$$
\mathbf{d}_{\text {Multigraph }}^{\emptyset}(n, t) \preccurlyeq t n^{2} .
$$

This bound consists in a continuous transition between the quadratic bound from Theorem 3.2.2 [17] when $t=0$ and the cubic bound from Theorem 3.1.3 [82] when $t=n$. The proof indeed combines the potentials from both proof.

In Theorem 5.4.2 [31], we provide a removal strategy for the case where there is only one point in $T$ to prove that

$$
\mathbf{d}_{|\mathrm{T}|=1 \text { Multigraph }}^{\mathrm{R}}(n, t) \preccurlyeq n \log |C|+t n \preccurlyeq n \log n+t n .
$$

In Theorem 5.5.2 [31], we provide a removal strategy for the case where there are two points in $T$, one inside and one outside the convex polygon formed by $C$, to prove that

$$
\mathbf{d}_{\text {Inout Multigraph }}^{\mathrm{R}}(n, t) \preccurlyeq t^{2} n+n \log n .
$$

[^5]In Theorem 5.6.1 [31], we provide a removal strategy for the case where there are two points in $T$, both lying inside the convex polygon formed by $C$, to prove that

$$
\mathbf{d}_{\text {Inin Multigraph }}^{\mathrm{R}}(n, t) \preccurlyeq t n+n \log n .
$$

In Theorem 5.7.1 [31], we provide a removal strategy for the case where there are two points in $T$, both lying outside the convex polygon formed by $C$, to prove that

$$
\mathbf{d}_{\text {Outout Multigraph }}^{\mathrm{R}}(n, t) \preccurlyeq t^{2} n+n \log n .
$$

In Theorem 6.2.1 [31], we provide an insertion strategy for the case where the points of $C$ lie in between two parallel lines while the points of $T$ lie outside this strip is only one point in $T$ to prove that

$$
\mathbf{d}_{\text {Separated Multigraph }}^{\mathrm{T}}(n, t) \preccurlyeq t|P| \log |C|+n \log |C| \preccurlyeq t n \log n .
$$

In Theorem 7.1.1 [31], we provide a strategy for both removal and insertion choices for the same case as Theorem 6.2.1 [31] (described in the previous paragraph) to prove that

$$
\mathbf{d}_{\text {Separated Multigraph }}^{\mathrm{RI}}(n, t) \preccurlyeq n+t|P| \preccurlyeq t n .
$$

In Theorem 7.2.3 [31], we provide a strategy for both removal and insertion choices for the case where all the points of $T$ lie outside the convex polygon formed by $C$ and where no endpoint is shared by more than one segment, to prove that

$$
\mathbf{d}_{\text {Allout Matching }}^{\mathrm{RI}}(n, t) \preccurlyeq t^{3} n \text {. }
$$

Counting flips without multiplicity. In all the previous upper bounds, using many times the same flip had to be counted accordingly in the performance. In Theorem 4.5.1 [30], we prove the sub-cubic $n^{8 / 3}$ upper bound on the number of distinct flips, that is, the number of flips where a flip used many times only count for one. This upper bound may become useful if combined with a strategy avoiding to use twice the same flip.

### 1.2.2 Lower Bounds

Lower bounds are very important as they are the only hint of how far our strategies may be from being optimal. In this dissertation, we show the following two lower bounds.

In Theorem 4.2.1 [33], we show that

$$
n^{2} \preccurlyeq \frac{3}{2} \frac{n(n-1)}{2}-\frac{n}{4} \leq \mathbf{d}_{\text {Redonaline Matching }}^{\emptyset}(n) .
$$

Previously to this result, the longest untangling process known used $\frac{n(n-1)}{2}$ flips and had the endpoints of the segments forming a convex polygon. This new lower bound, even though roughly similar, disproves the intuition that the longest untangling process occurs when the endpoints of the segments form a convex polygon.

In Theorem 5.1.1 [33], we show that

$$
n \preccurlyeq \frac{3}{2} n-2 \leq \mathbf{d}_{\text {Convex Bipartite Matching }}^{\mathrm{R}}(n) .
$$

It is the first lower bound on $\mathbf{d}^{\boldsymbol{R}}$ that is greater than $n$.

### 1.2.3 Reductions

All these bounds may seem very specialized to a specific version of $\mathbf{d}$ at first sight, but most of them carry over to a number of other version of $\mathbf{d}$ using the following four reduction results. Lemma 2.3.1 essentially states that the more choice we have, the shorter the untangling process. Lemma 2.3.2 essentially states that the stronger the property to be preserved, the shorter the untangling process. Lemma 2.3.3 roughly states that preserving a weaker property in exchange of more choice may lead to shorter untangling processes. Theorem 4.1.1 [30] implies that essentially all the versions of $\mathbf{d}^{\natural}$ are roughly the same. We highlight our contributions and summarize all the upper and lower bounds on all the versions of $\mathbf{d}$, including all the bounds derived thanks to reductions (the original theorems are marked in bold), in Table 1.1 and Table 1.2 for the Multigraph versions, in Table 1.3 and Table 1.4 for the Matching versions, in Table 1.5 for the Bipartite Matching versions, in Table 1.6 for the Cycle versions, and in Table 1.7 for the Tree versions. All these tables are in Section 1.6 at the end of this chapter.

### 1.2.4 Intractability

All the contributions presented so far are related to d, i.e. to counting flips. In contrast, this last contribution is about counting time. In the version of the problem where half of the points are red and the other half is blue, and where a segment must match a red point to a blue point, we show in Theorem 8.0.1 that it is not possible (unless $\mathcal{P}=\mathcal{N} \mathcal{P}$ ) to compute the shortest possible untangle process of a given set of segments within a reasonable (i.e., polynomial) time.

### 1.3 Organization

This dissertation is organized into nine chapters.
Chapter 1 is the present introduction, where we first introduce the problematic, mention the contributions, describe the organization, then we present related reconfiguration problems.

Chapter 2 states the assumptions and provides definitions and lemmas used intensively throughout the dissertation.

Chapter 3 presents the literature results falling in the problematic of this dissertation, providing proofs and generalisations for most of them. In contrast with the general organization by choice, the sections of Chapter 3 are organized by point set property, highlighting the fact that choice did not benefit from a systematic treatment until now.

The rest of the chapters presents the contributions of this dissertation.
Chapter 4 is dedicated to untangle sequences with no choice. We first prove that all the versions of $\mathbf{d}^{\natural}$ have the same asymptotic behaviour. Then we prove one lower bound and two upper bounds on various versions of $\mathbf{d}^{\natural}$. Finally, we prove a sub-cubic upper bound on the number of distinct flips in an untangle sequence.

Chapter 5 is dedicated to untangle sequences with removal choice. We prove one lower bound and seven upper bounds on various versions of $\mathbf{d}^{R}$.

Chapter 6 is dedicated to untangle sequences with insertion choice. We prove two upper bounds on two different versions of $\mathbf{d}^{\mathrm{I}}$.

Chapter 7 is dedicated to untangle sequences with both removal and insertion choices. We prove two upper bounds on two different versions of $\mathbf{d}^{\mathrm{RI}}$.

Chapter 8 is dedicated to proving that any constant factor approximation of the length of the shortest untangle sequence in the Bipartite Matching version is $\mathcal{N P}$-hard.

Chapter 9 contains some elements of discussion about the open problems raised by the problematic of the dissertation. In particular, we give some insight on the difficulties to extend known results, we provide counter-examples to some ideas, and we discuss about what we believe to be interesting ideas to tackle some of the open problems.

### 1.4 Related Reconfiguration Problems

Untangling segments is one of a wide range of problems which share a common setting: the reconfiguration problems. A reconfiguration problem always comes with a graph, called the reconfiguration graph, where the vertices are combinatorial or geometrical objects called the configurations (in our case, the multisets of segments satisfying a given property on a given point set), and where there is a directed edge from a configuration to another if there exists a reconfiguration (in our case, a flip) transforming the first into the second (Figure 1.5). Some typical questions are to find whether this reconfiguration graph is connected, to find its diameter and the length of the longest path (for an overview on reconfiguration see for example [20, 60, 81]). Reconfiguration may be used to progressively improve the quality of a solution to a given problem (like in this dissertation, to shorten the length of a tour) or to enumerate efficiently all the solutions of a problem (see for example [54] for an enumeration of crossing-free tours with special visibility properties). In this section, we present some reconfiguration problems related to ours.

Figure 1.5: The reconfiguration graph of the point set from Figure 1.1(a) for flips in the Cycle version. The tours displayed in the same column have the same number of crossings, and are sorted by decreasing length.

Opt reconfiguration. One could wonder about also allowing a non-crossing pair of segments to be replaced as long as the total length of the segments is shortened. This relaxed operation, called a 2 -opt change, is used in a class of approximation algorithms for the TSP. Note that both flips and 2-opt changes are special cases of 2-changes. A 2 -change has the same definition as a flip except that the condition that the removed segments cross is dropped (no geometry is involved anymore).

The apparent similarity with flips is misleading. A striking contrast is that there exist sequences with an exponential number of 2-opt changes [42].

Moreover, 2-opt changes depend only on the order of the pairs of segments with endpoints in $P$ sorted by increasing total length (induced by the metric on $P$ ) whereas flips depend only on the set of crossing pairs of segments with endpoint in $P$ (called the crossing type or the $x$-type of $P$ in the literature [73], the crossing type of $P$ is induced by the order type of $P$ ). In more concrete terms, a perturbation of the coordinates may turn a 2 -opt change into a 2 -change which is not a 2 -opt change while preserving the set of crossing pairs of segments with endpoint in $P$ (and the order type of $P$ ). We discuss about crossing types in Section 1.5.

As it is a fortiori the case with flips, it is not enough to find an optimal tour ( [61], page 18).

The length of a 2-optimal tour in a metric TSP instance with $n$ cities is at most $\sqrt{n / 2}$ times the length of a shortest tour and this bound is tight. The approximation ratio of the 2-Opt Heuristic for the metric TSP is $\sqrt{n / 2}$ [56].

Triangulation reconfiguration. Reconfiguration problems in the context of triangulations are widely studied [71]. A reconfiguration consists of removing one edge and adding another one while preserving a triangulation. It is known that $\Theta\left(n^{2}\right)$ reconfigurations are sufficient and sometimes necessary to obtain a Delaunay triangulation [57, 64]. Determining the reconfiguration distance between two triangulations of a point set [68,75] and between two triangulations of a simple polygon [6] are both $\mathcal{N}$-hard.

Planar tree reconfiguration. The planar tree reconfigurations are similarly to triangulation reconfigurations. A reconfiguration consists of removing one edge and adding another one while preserving a tree [3].

Planar path, a special class of planar trees, have also been studied. It is possible to reconfigure any two non-crossing paths if the points are in convex position [8, 23] or if there is one point inside the convex hull [4].

Multigraph reconfiguration. It is possible to relax the flip definition to all operations that replace two segments by two others with the same four endpoints, whether they cross or not, and generalize the configurations to multigraphs with the same degree sequence $[52,53,60]$. In this context, finding the shortest path from a given configuration to another in the reconfiguration graph is $\mathcal{N} \mathcal{P}$-hard, yet 1.5 -approximable [14, 15, 45, 84]. If we additionally require the configurations to be connected graphs, the same problem is $\mathcal{N P}$-hard and 2.5 -approximable [21].

Considering perfect matchings of an arbitrary graph (instead of the complete graph), a flip amounts to exchanging the edges in an alternating cycle of length four. It is
then PSPACE-complete to decide whether there exists a path from a configuration to another [18]. There is, actually, a wide variety of reconfiguration contexts derived from $\mathcal{N} \mathcal{P}$-complete problems where this same accessibility problem is PSPACE-complete [59].

### 1.5 Contextual Problems

In this section, we gather some pieces of answer to some relevant questions about untangling segments.

Searching for crossings. Before performing a flip on a multiset $S$ of $n$ segments, we have to search for crossing pairs of segments. The time taken by this search is not taken into account in our flip count; it is nonetheless important to mention the time (and space) complexity of this search.

To find all the crossings of a multiset of segments, we may use Ivan J. Balaban's algorithm [11] asymptotically optimal both in time, $O(k+n \log n)$ where $k$ is the number of intersecting pairs of segments, and space, $O(n) .{ }^{12}$ In practice, the Bentley-Ottmann sweep line algorithm [13] is often preferred because it is easier to implement and its space complexity is $O(n)$, even though its time complexity $O((k+n) \log n)$ is not asymptotically optimal. ${ }^{13}$

If we are not interested in choosing a crossing pair, but only in finding one, then the Shamos-Hoey algorithm [77] running in $O(n \log n)$ time is enough. This algorithm is in fact the precursor of the Bentley-Ottmann algorithm.

However, if $O(n m)=O\left(n^{2}\right)$ space is not too much to ask ( $m$ being the maximum number of crossings appearing on the same segment of $S$ during the untangling process), then we may maintain for each segment $s \in S$ a list of all the segments crossing $s$. This list is initialized, say, using Ivan J. Balaban's algorithm. Then, at each flip, we remove two segments together with their list of crossings, and we insert two segments and build their list of crossings in $O(n)$. This process only adds a $O(n)$ time overhead at each flip and a preprocessing time of $O(k+n \log n)=O\left(n^{2}\right)$ (where $k$ is the number of crossings in the initial multiset $S$ ).

This considerations about the time (and space) overhead induced by the search for crossings does not include the time (and space) overhead induced by the computation of removal and insertion choices which depends on the strategy used. All the insertion strategies presented in this dissertation run in constant time and space per flip. All the removal strategies and all the strategies for both removal and insertion presented in this dissertation run in at most quadratic time (to search for the right crossing pair to remove among the crossings we have computed) and constant space per flip. This rough upper bound may be improved by analyzing each strategy.

[^6]Computing crossing-free segments without flips. We mentioned that untangling a tour remains the only known way to compute in polynomial time a crossing-free tour of shorter length. However, it is not the case for matchings, bipartite matchings, and trees where faster algorithms are available. Next, we mention several of these computational geometry algorithms (for an introduction to computational geometry, see for instance [16]).

A simple sweep line algorithm is enough to compute a crossing-free matching on $2 n$ points ${ }^{14}$ in $O(n \log n)$ time: sort the points by increasing $x$ coordinates and connect every other point to the next one. Notice that the minimal-weight perfect matching computed in $O\left(n^{3}\right)$ time [47] by Edmonds' blossom algorithm [40, 41] is also crossing free. This algorithm is used as a subroutine in Christofides-Serdyukov approximation algorithm for the metric TSP.

Given a bipartite point set of $2 n$ points, ${ }^{14}$ Edmonds' blossom algorithm (in the bipartite complete graph instead of the complete graph) also yields a crossing-free bipartite matching in $O\left(n^{3}\right)$ time. Yet, such a crossing-free bipartite matching can be computed in optimal $O(n \log n)$ time and optimal $O(n)$ space [55]. The algorithm is based on semi-dynamic convex hull data structures and does not use flips. Note that recursively computing a ham-sandwich cut of a bipartite point set of $2 n$ points in optimal $O(n)$ time $[66,67]$ also yields an optimal $O(n \log n)$ time algorithm to compute a crossing-free bipartite matching. ${ }^{15}$

The 2-dimension Euclidean minimum spanning tree of $n+1$ points ${ }^{14}$ can also be computed in optimal $O(n \log n)$ time: compute the Delaunay triangulation in $O(n \log n)$ time $[38,50,65]$, then run a graph minimum spanning tree algorithm, say Kruskal's algorithm in $O(m \log n)$ time (where $m$ is the number of edges) [63], on this Delaunay triangulation graph with its $O(n)$ edges weighted with their length. However, we do not have control on the degree of each point of the minimum spanning tree. In fact, computing the spanning tree of minimum total distance with the degree of each point imposed is $\mathcal{N} \mathcal{P}$-hard (by reduction of the Hamiltonian path problem). To compute a crossing-free spanning tree on a point set where the degree of each point is imposed, the untangling process may be a good option.

From point sets to crossing types. We have presented the set $P$ of endpoints of the segments as a part of the input of the untangling problem, but the actual coordinates of the points of $P$ are not required if the set of all the crossing pairs of segments between any two points of $P$ is provided. More precisely, we say that two sets of labeled points $P_{1}$ and $P_{2}$ have the same labeled crossing type if their set of crossing pairs of segments both corresponds to the same set of unordered pairs of unordered pairs of labels ${ }^{16}$. We say that two sets of points $P_{1}$ and $P_{2}$ have the same crossing type (crossing types are also called x-types in the literature) if there exist labels for each of $P_{1}$ and $P_{2}$ such that $P_{1}$ and $P_{2}$ have the same labeled crossing type. The untangling problem depends only

[^7]on the crossing type of the point set. Therefore, properties such as having endpoints in convex position should be thought of as having endpoints with the same crossing type as a point set in convex position.

The crossing type of a point set $P$ may be derived from the order type of $P$, which is defined similarly to the crossing type, replacing "the set of all the crossing pairs of segments between any two points of $P$ " by "the set of all the orientations of any three points of $P "$ (three labeled points have three possible orientations: clockwise, counterclockwise, and colinear but this last is excluded by our general position assumption). Crossing types and order types benefit a wide range of applications but raise difficult problems such as counting, enumerating, sampling, finding (integer) coordinate representations, characterizing. They are actively studied (for example see [5] for a reconstruction of all the order types of a given list of cyclic orders, see [73] for an algorithm reconstructing the crossing type of a point set from its planar spanning trees organised in a reconfiguration graph). Order types have been enumerated up to 11 points [2]. However, it does not seem practical to test conjectures from our untangling problem using these first enumerated order types.

### 1.6 Summary Tables

This section contains tables summarizing all the bounds on all the versions of d. Each cell in the tables contains an asymptotic lower or upper bound on $\mathbf{d}_{\Pi_{1}}^{\text {Choices }}(n)$ for Choices $\in\{\emptyset, R, I, R I\}$ specified in the column, for $\Pi_{1}$ specified in the line, and for $\Pi$ specified in the title of the table, with a reference to the corresponding theorem just bellow. Sometimes an asymptotic bound follows from more than one theorems, in which case they are all mentioned.

We use normal font for the bounds which are only a corollary of the theorems specified via some reductions (Lemma 2.3.1, Lemma 2.3.2, Lemma 2.3.3, and Theorem 4.1.1 [30]). We use bold font for the theorem bounds themselves. When an asymptotic bound is both a theorem and a corollary of another theorem, both theorems are mentioned but only the former is bold. A cell is highlighted when a contribution is involved (i.e., when the theorem proving the cell bound with the best constants is a contribution).

The reductions often transfer the upper bound of a given cell to the upper bound cells on its left, to the upper bound cells bellow, and to the corresponding upper bound cell in a table bellow. Conversely, the reductions often transfer the lower bound of a given cell to the lower bound cells on its right, to the lower bound cells above, and to the corresponding lower bound cell in a table above.

We recall the notation for the different types of choice.
$\emptyset:$ No choice, which means the longest untangle sequence.
R: Removal choice.
I: Insertion choice.
RI: Both removal and insertion choices.

We also recall the notation for the different types of point sets.

-C $\cup \mathrm{T}:$ The endpoints are partitioned into a set $C$ in convex position and a general set $T$.
 a set $T$ outside the convex hull of $C$.

थ. Separated: The endpoints are partitioned into a set $C$ in convex position and a set $T$ outside the convex hull of $C$ such that $T$ and $C$ are separated by two parallel lines.
. Outout: The endpoints are partitioned into a set $C$ in convex position and a set $T$ containing two points outside the convex hull of $C$.

Inout: The endpoints are partitioned into a set $C$ in convex position and a set $T$ with one point inside and one point outside the convex hull of $C$.

- Inin: The endpoints are partitioned into a set $C$ in convex position and a set $T$ containing two points inside the convex hull of $C$.
- $|\mathrm{T}|=1$ : The endpoints are partitioned into a set $C$ in convex position and a set $T$ containing one point.

- ${ }^{\circ}$ 。Redonaline: The red endpoints are on a line and the blue points are above - = this line.

Permutation: The endpoints are on two parallel lines, one containing red points and the other blue points.

### 1.6.1 Multigraph

Multigraph Version with Both Choices and Insertion Choice

Table 1.1: Asymptotic lower and upper bounds on $\mathbf{d}_{\Pi}$ Choices Multigraph for the property $\Pi$ of the point set $P=C \cup T$ specified in each line and for the Choices is specified in each column.

## Chapter 2

## Preliminaries

This chapter is a collection of assumptions, definitions, and lemmas used throughout this dissertation.

### 2.1 Assumptions

In the following, we summarize the assumptions implicitly used throughout this dissertation.

Notation abuses. We often omit the braces around sets defined extensively, especially for pairs of segments which are to be understood as unordered pairs, i.e., sets of exactly two segments.

Asymptotic bounds incorrectly fading to zero. Our bounds often have terms like $O(t n)$ and $O(n \log |C|)$ that would incorrectly become 0 if $t$ or $\log |C|$ is 0 . In order to avoid this problem, factors in the $O$ notation should be made at least 1. For example, the aforementioned bounds should be respectively interpreted as $O((1+t) n)$ and $O(n \log (2+|C|))$.

General position. Throughout this dissertation, and unless mentioned otherwise, we assume general position of the endpoints of the segments we consider, meaning that any three endpoints are assumed to not be colinear. We also assume that the two endpoints of a segment are distinct. The only time we drop these two assumptions is in the proof of Theorem 3.1.3 [19, 82]. In the proofs of Theorem 3.1.4 [19], Theorem 5.8.1 [33], Theorem 6.2.1 [31], and of Theorem 7.1.1 [31], we extend our standard general position assumptions to also exclude pairs of endpoints with the same $y$-coordinate.

### 2.2 Definitions

In the following, we summarize important definitions used throughout this dissertation.
Segment types. Given two (possibly equal) sets $P_{1}, P_{2}$ of endpoints, we say that a segment is a $P_{1} P_{2}$-segment if one of its endpoints is in $P_{1}$ and the other is in $P_{2}$.

Crossings. We say that two segments cross if they intersect at a single point which is not an endpoint of either segment. A pair of crossing segments is called a crossing. We also say that a line and a segment cross if they intersect at a single point which is not an endpoint of the segment.

If $h$ is a segment or a line (respectively a set of two lines) we say that $h$ separates a set of points $P$ if $P$ can be partitioned into two non-empty sets $P_{1}, P_{2}$ such that every segment $p_{1} p_{2}$ with $p_{1} \in P_{1}, p_{2} \in P_{2}$ crosses $h$ (respectively crosses at least one of the lines in $h$ ).

General position implies that two intersecting segments may either cross or share at least one endpoint. To fully remove any self-intersection of a tour without any assumption, other types of intersecting pairs of segments have been considered in [82]. We discuss this matter in Section 3.1.1.

Flips. A flip $f$ in the $\Pi$ version removing the crossing segments $s_{1}, s_{2}$ and inserting the non-crossing segments $s_{1}^{\prime}, s_{2}^{\prime}$ with the same four endpoints is defined as the function that maps any set of segments $S$ satisfying $\Pi$, containing $s_{1}$ and $s_{2}$, and such that $S \cup\left\{s_{1}^{\prime}, s_{2}^{\prime}\right\} \backslash\left\{s_{1}, s_{2}\right\}$ also satisfies $\Pi$, to $f(S)=S \cup\left\{s_{1}^{\prime}, s_{2}^{\prime}\right\} \backslash\left\{s_{1}, s_{2}\right\}$.

Parameters. The main parameter in all the bounds in this dissertation is $n$, defined as $|S|$, the number of segments (counted with multiplicity) in the multiset of segments $S$ to be untangled. In the following, we define another parameter used in this dissertation.

Any point set $P$ may be partitioned into $P=C \cup T$ where $C$ is in convex position even if it means that $C$ or $T$ is empty. In this context, we define the parameter $t$ as the number of segments with at least one endpoint in $T$ (the segments with two endpoints in $T$ are counted twice). The parameter $t$ may equivalently be defined as the sum of the degrees of the points in $T$. In this dissertation, the bounds involving $t$ get better when $t$ is small. It is therefore best to choose the partition $P=C \cup T$ so as to minimize $t$ (this choice may be different from choosing $C$ to be the points defining the convex hull of $P$ ).

We also provide fine grain parameterized bounds using the following parameters: $|P|,|C|,|T|$.

Properties. We freely interpret a multiset $S$ of $n$ segments with endpoints $P$ in the plane as the multigraph $(P, S)$ where the set of vertices is the set of endpoints and where the multiset of edges is the multiset of segments. Next, we give names to the properties $\Pi$ which are considered in this dissertation. We classify these properties into the following three types.

1. The point set properties are the properties about the position of the endpoints (note that they are also preserved by any insertion choice at every flip).
2. The insertion properties consist of the empty (i.e., always true) property and of the properties that impose which pair is inserted at every ${ }^{1}$ flip.

[^8]3. The degree properties are constraints on the degree of each point (note that they are preserved by any insertion choice at every flip).

The point set properties (also preserved by any insertion choice) considered is this dissertation are the following (see Figure 1.4 or the beginning of Section 1.6):

- General: the empty property, i.e., the property which is always true (having a general point set is a given). This notation is only used in the tables of Section 1.6.
- $\mathrm{C} \cup \mathrm{T}$ : the empty property (any point set $P$ may be partitioned into $P=C \cup T$ where $C$ is in convex position even if it means that $C$ or $T$ is empty). This notation is only used in the tables of Section 1.6 to indicate that the bounds are parameterized by $t$, the sum of the degrees of the points in $T$.
- Convex: having a point set in convex position.
- Permutation: having a bipartite point set in convex position such that the red points are separated from the blue points by a line.
- Redonaline: having a bipartite point set with red points on the $x$-axis and blue points above.
- $|\mathrm{T}|=\mathrm{k}$ : having a point set partitioned as $P=C \cup T$ with $C$ in convex position and $|T|=k$.
- Inout: having a $|\mathrm{T}|=2$ point set with the one point of $T$ inside the convex hull of $C$, and the other point of $T$ outside.
- Inin: having a $|\mathrm{T}|=2$ point set with the two points of $T$ inside the convex hull of $C$.
- Outout: having a $|\mathrm{T}|=2$ point set with the two points of $T$ outside the convex hull of $C$.
- Allout: having a point set partitioned as $P=C \cup T$ with $C$ in convex position and all the points of $T$ outside the convex hull of $C$.
- Separated: having an Allout point set partitioned as $P=C \cup T$ with $C$ in convex position and separated from $T$ by two parallel lines.

The insertion properties defining which pair of segments to insert for every flip considered is this dissertation are the following:

- Multigraph: the empty property (being a multigraph is a given).
- Bipartite: being bipartite for a given partition of the point set.
- Cycle: being a cycle, i.e., being a tour.
- Tree: being a tree.

The only degree property (preserved by any insertion choice) considered is this dissertation is the following:

- Matching: being a matching.

All these properties may be combined as in Convex Bipartite Matching; spaces stands for conjunctions and we may omit the empty property or a property that is inferred by the rest.

The flip graph and the choice graph. Consider a property $\Pi=\Pi_{1} \Pi_{2} \Pi_{3}$ being the conjunction of a point set property $\Pi_{1}$, an insertion property $\Pi_{2}$, and a degree property $\Pi_{3}$. Given a point set $P$ satisfying $\Pi_{1}$ and a function $d^{\circ}: P \rightarrow \mathbb{N}^{*}$ satisfying $\Pi_{3}$, the fip graph of $\left(P, d^{\circ}, \Pi_{2}\right)$ is the directed simple graph defined as follows. The set of vertices $V^{\mathrm{R}}$ consists of all the multigraphs satisfying $\Pi_{2}$ with vertices $P$ and a degree function equal to $d^{\circ}$. There is a directed arc from a multigraph $S_{1} \in V^{\mathrm{R}}$ to a multigraph $S_{2} \in V^{\mathrm{R}}$ if there exists a flip in the $\Pi_{2}$ version transforming $S_{1}$ into $S_{2}$.

Figure 2.1: The choice graph of a six-point set for flips in the Matching version. The vertices of $V^{\mathrm{R}}$ are represented by big grey circles containing the corresponding matching. The vertices of $V^{\mathrm{I}}$ are represented by small grey circles.

The choice graph of $\left(P, d^{\circ}, \Pi_{2}\right)$ is the directed simple graph constructed from the flip graph of $\left(P, d^{\circ}, \Pi_{2}\right)$ by decomposing each arc into two arcs with an extra vertex representing a multigraph after removal and before insertion. Specifically, given a class $K$ of multigraphs satisfying $\Pi$, let $\widehat{K}$ be the class of all the multigraphs obtained from the multigraphs of $K$ by applying only the removal part of the flips in the $\Pi_{2}$ version. The vertices of the choice graph are $V^{\mathrm{R}} \cup V^{\mathrm{I}}$ where $V^{\mathrm{I}}=\widehat{V^{\mathrm{R}}}$. For each directed arc from a multigraph $S_{1} \in V^{\mathrm{R}}$ to a multigraph $S_{2} \in V^{\mathrm{R}}$ in the flip graph, there are two directed arcs in the choice graph: the directed arc from $S_{1}$ to $S_{1}^{\prime} \in V^{\mathrm{I}}$ where $S_{1}^{\prime}$ is the multigraph obtained from $S_{1}$ by applying only the removal part of the flip, and the directed arc from $S_{1}^{\prime}$ to $S_{2}$.

The flip graphs (respectively the choice graphs) in the $\Pi$ version are the flip graphs (respectively the choice graphs) of ( $P, d^{\circ}, \Pi_{3}$ ) for all possible $P$ satisfying $\Pi_{1}$ and all possible $d^{\circ}$ satisfying $\Pi_{2}$.

Figure 1.5 displays an example of a flip graph. Figure 2.1 displays an example of a choice graph; this example has no removal choice which is not the general situation, but allows a better readability.

Strategies. We define a removal strategy in the $\Pi$ version to reach a class $K$ of multigraphs as a function mapping each choice graph in the $\Pi$ version and each vertex $S$ in $V^{\mathrm{R}} \backslash K$ of this choice graph to one of the arcs from $S$.

We define an insertion strategy in the $\Pi$ version to reach a class $K$ of multigraphs as a function mapping each choice graph in the $\Pi$ version and each vertex $S$ in $V^{\mathrm{I}} \backslash \widehat{K}$ of this choice graph to one of the arcs from $S$. Note that there exists exactly one insertion strategy if $\Pi_{3}$ is not empty.

A strategy for both removal and insertion choices in the $\Pi$ version to reach a class $K$ consists of a removal strategy and an insertion strategy in the $\Pi$ version to reach a class $K$.

The class $K$ always includes the class of crossing-free multigraphs satisfying $\Pi$; it is most of the time taken to be equal.

Untangle sequences. A sequence of multisets $S_{0}, \ldots, S_{k}$ is called a flip sequence (in the $\Pi$ version) and $k$ is called its length if $S_{0}$ satisfies $\Pi$ and if for each $i \in\{1, \ldots, k\}$, there exists a flip $f_{i}$ (in the $\Pi$ version) such that $S_{i}=f i\left(S_{i-1}\right)$. In other words, a flip sequence is a path in the flip graph.

A flip sequence (in the $\Pi$ version) $S_{0}, \ldots, S_{k}$ is called an untangle sequence (in the $\Pi$ version) if $S_{k}$ is crossing free.

Note that a multiset $S_{0}$ satisfying $\Pi$, a removal strategy in the $\Pi$ version to reach a class $K$ of multigraphs, and, if $\Pi$ is preserved by any the insertion choices, an insertion strategy in the $\Pi$ version to reach a class $K$ of multigraphs determine a unique flip sequence, and the final multigraph is in $K$.

The unknown of this dissertation. Consider a property $\Pi=\Pi_{1} \Pi_{2} \Pi_{3}$ being the conjunction of a point set property $\Pi_{1}$, an insertion property $\Pi_{2}$, and a degree property $\Pi_{3}$. Let $n$ be a non-negative integer. In the following four definitions, $k(S, r, i)$ denotes the length of the untangle sequence starting at the multiset $S$ of $n$ segments (satisfying $\Pi$ ) and determined by the removal strategy r (in the $\Pi$ version to reach the class of crossing-free multigraphs) and by the insertion strategy i (in the $\Pi$ version to reach the class of crossing-free multigraphs).

$$
\begin{aligned}
\mathbf{d}_{\Pi}^{\emptyset}(n) & =\max _{S} \max _{r} \max _{\mathbf{i}} k(S, \mathrm{r}, \mathrm{i}) \\
\mathbf{d}_{\Pi}^{\mathrm{R}}(n) & =\max _{S} \min _{\mathrm{r}} \max _{\mathrm{i}} k(S, \mathrm{r}, \mathrm{i}) \\
\mathbf{d}_{\Pi}^{\mathrm{I}}(n) & =\max _{S} \max _{r} \min _{\mathrm{i}} k(S, \mathrm{r}, \mathrm{i}) \quad \text { (defined only if the insertion property } \Pi_{2} \text { is empty) } \\
\mathbf{d}_{\Pi}^{\mathrm{RI}}(n) & =\max _{S} \min _{\mathrm{r}} \min _{\mathrm{i}} k(S, \mathrm{r}, \mathrm{i}) \quad \text { (defined only if the insertion property } \Pi_{2} \text { is empty) }
\end{aligned}
$$

It is convenient to imagine that two clever players, let us call them the oracle and the adversary, are playing the following game using the choice graph as a board. The adversary chooses the starting vertex in $V^{\mathrm{R}}$. A game builds a path in the choice graph arc by arc until a crossing-free vertex is reached. The oracle aims at minimizing the length of the path while the adversary aims at maximizing this length. The four definitions corresponds to the length of this resulting path with different choices for
the oracle (specified in the exponent). This length is $\mathbf{d}^{\emptyset}$ if the adversary performs all the choices to be done, it is $\mathbf{d}^{\mathrm{R}}$ if the oracle performs all the removal choices while the adversary performs all the remaining choices, it is $\mathbf{d}^{\mathrm{I}}$ if the oracle performs all the insertion choices while the adversary performs all the remaining choices, it is $\mathbf{d}^{\mathrm{RI}}$ if the oracle performs all the removal and all the insertion choices (the adversary only get to choose the starting vertex).

Notice that we define $\mathbf{d}_{\Pi}^{\mathrm{I}}$ and $\mathbf{d}_{\Pi}^{\mathrm{RI}}$ only if $\Pi_{2}$ is empty. Indeed, it is important for the proof of Lemma 2.3.2 that all the occurrences of the choices specified in the exponent are performed by the oracle. This is also the reason why we do not consider properties such as "admitting a given coloring" where the given coloring has more than two colors (preserving such a property sets the insertion choice of only certain flips).

### 2.3 Reductions

In this section, we prove general inequalities between the different versions of $\mathbf{d}$.
Lemma 2.3.1 (choice reduction). The following inequalities hold for any non-negative integer $n$, and for any property $\Pi$.

$$
\mathbf{d}_{\Pi}^{\mathrm{RI}}(n) \leq\left\{\begin{array}{l}
\mathbf{d}_{\boldsymbol{\Pi}}^{\mathrm{R}}(n) \\
\mathbf{d}_{\Pi}^{\mathrm{T}}(n)
\end{array}\right\} \leq \mathbf{d}_{\Pi}^{\emptyset}(n)
$$

Proof. The more choice untangle sequences have, the shorter, hence the inequalities.
Lemma 2.3.2 (property reduction). The following inequality holds for any non-negative integer $n$, for any two properties $\Pi, \Pi^{\prime}$ such that $\Pi \Longrightarrow \Pi^{\prime}$, and for any Choices $\in$ $\{\emptyset, R, I, R I\}$.

$$
\mathbf{d}_{\Pi}^{\text {Choices }}(n) \leq \mathbf{d}_{\Pi^{\prime}}^{\text {Choices }}(n)
$$

Proof. First notice that any untangle sequence in the $\Pi$ version is also a untangle sequence in the $\Pi^{\prime}$ version.

We show that going from $\mathbf{d}_{\Pi}^{\text {Choices }}(n)$ to $\mathbf{d}_{\Pi^{\prime}}^{\text {Choices }}(n)$ gives more choice to the adversary while leaving the oracle with essentially the same choice. The adversary may prevent the oracle to benefit from the untangle sequences in the $\Pi^{\prime}$ version which are no in the $\Pi$ version by choosing the starting multiset of segment. In the case where Choices $\in\{\emptyset, R\}$, some insertion choices which were set to preserve property $\Pi$ may not be set to preserve property $\Pi^{\prime}$ anymore. Let us call this phenomenon insertion choice relaxation. Therefore, the adversary may also gains choice from insertion choice relaxation. Note that, by definition of $\mathbf{d}^{\text {Choices }}$ and in contrast with the adversary, the oracle does not gain any choice because of insertion choice relaxation.

Thus, the inequality holds for any Choices $\in\{\emptyset, R, I, R I\}$.
Lemma 2.3.3 (transfer reduction). The following inequalities hold for any non-negative integer $n$, and for any property $\Pi$ such that preserving $\Pi$ does not set insertion choice.

$$
\begin{aligned}
& \mathbf{d}_{\Pi \text { Matching }}^{\mathrm{RI}}(n) \leq \mathbf{d}_{\Pi \text { Bipartite Matching }}^{\mathrm{R}}(n) \\
& \mathbf{d}_{\Pi \text { Matching }}^{\mathrm{T}}(n) \leq \mathbf{d}_{\Pi \text { Bipartite Matching }}^{\emptyset}(n)
\end{aligned}
$$

Proof. Going from $\mathbf{d}_{\Pi}^{\mathrm{RI}}{ }_{\text {Matching }}(n)$ (respectively $\mathbf{d}_{\Pi}^{\mathrm{T}}$ Matching $(n)$ ) to $\mathbf{d}_{\Pi}^{\mathrm{R}}$ Bipartite Matching $(n)$ (respectively $\mathbf{d}_{\Pi}^{\emptyset} \operatorname{Bipartite}^{\operatorname{Matching}}(n)$ ), we transfer insertion choice from the oracle to preserving the Bipartite property. Any matching being 2-colorable, the adversary keeps the same choice in the starting matching (respectively in the starting matching and in removal choices), yielding the two inequalities.

### 2.4 Triangle Argument

The following simple fact, first stated informally then as a lemma without proof, is used in many of the proofs presented in this dissertation. We refer to it (or its contraposition) as the triangle argument or implicitly use it.
"If a line enters a triangle through one edge, then it must leave through another edge."

Lemma 2.4.1 (triangle argument). If a line $\ell$ crosses the edge pq of a (possibly flat) triangle pqo, then $\ell$ intersects $(p o \cup q o) \backslash\{p, q\}$, the union of the two other edges excluding $p$ and $q$, at exactly one point.

### 2.5 Potential Argument

In this section, we state another simple lemma which is also used in many proofs throughout this dissertation.

Lemma 2.5.1 (potential argument). Let $\varphi: I \rightarrow J$ be a function. If $J$ is a finite set and if, for all $j \in J, \varphi^{-1}(\{j\})$ is a finite set, then $I$ is a finite set and we have the following identity.

$$
|I|=\sum_{j \in J}\left|\varphi^{-1}(\{j\})\right|
$$

In this context, we call the function $\varphi$ a potential. Our most frequent use of Lemma 2.5.1 is when $J$ is an integer interval and $\varphi$ is decreasing to upper bound the length $|I|$ of a sequence (e.g., a flip sequence) $\left(S_{i}\right)_{i \in I}$ by $|J|$. Intuitively, the potential of a step of a process intend to measure how far this step is from the end of the process (e.g., from being crossing free), and a decrease of potential intend to measure the progress made by each step of the process (e.g., each flip).

### 2.6 Splitting Lemma

The notion of splitting first appears in [19] (see the proof of Theorem 3.2.12 [19]), then in [33], and in [31] where the notion is generalized. In the following, we first give this generalized definition of splitting, then state the corresponding lemma, and finally give some examples.

Consider a finite point set $P$ decomposed into $P=\bigcup_{i=1}^{k} P_{i}$ (this decomposition is not necessarily a partition). We say that the decomposition $\bigcup_{i=1}^{k} P_{i}$ splits the point set
$P$ if no segment of $\binom{P_{i}}{2}$ crosses a segment of $\binom{P_{j}}{2}$ for all $i \neq j$. Now, consider a finite multiset $S$ of segments partitioned into $S=\bigcup_{i=1}^{k} S_{i}$ and let $P$ be the set of endpoints of $S$ and $P_{i}$ be the set of endpoints of $S_{i}$. We say that the partition $\bigcup_{i=1}^{k} S_{i}$ splits the multiset $S$ if the decomposition $\bigcup_{i=1}^{k} P_{i}$ splits the point set $P$ (Figure 2.2). In the Bipartite version where the point set is partitioned into red and blue points, we refine these definitions as follows. We say that the decomposition $\bigcup_{i=1}^{k} P_{i}$ splits the point set $P$ if no segment of $\binom{P_{i}}{2}$ with one red endpoint and one blue endpoint crosses a segment of $\binom{P_{j}}{2}$ with one red endpoint and one blue endpoint for all $i \neq j$ (Figure 2.2(e)). ${ }^{2}$

The following two facts imply Lemma 2.6.1 sated next.

- The four endpoints of the removed and inserted segments of any flip of $S$ all belong to the same $P_{i}$ for some $i$.
- If $f_{i}$ is a flip of $S_{i}$ and $f_{j}$ is a flip of $S_{j}$, then they commute, i.e., $f_{i}\left(f_{j}(S)\right)=$ $f_{j}\left(f_{i}(S)\right)$.
Lemma 2.6.1 (splitting; [19, 31]). Consider a partition $S=\bigcup_{i=1}^{k} S_{i}$ splitting a finite multiset $S$ of segments.

A sequence of flips applied to $S$ is partitioned into $k$ subsequences, the $i$-th subsequence consisting of all the flips which apply to $S_{i}$, and these subsequences commute in the sens that any fip in one subsequence commutes with a fip in another subsequence.

Figure 2.2: Examples of splitting partitions of multisets of segments where each partition is shaded and where the segments inserted in some flip sequence are dashed. Each occurrence of the segment $s$ is uncrossable. (a) The line $\ell$ splits the segments in three partitions, one of which consisting of the segment $s$ alone. (b) A partition which is not induced by any line splitting the segments in three. (c) Crossing-free segments, each of them forming its own partition for splitting. (d) A partition splitting the segments in two. One partition consists of the segment $s$ alone (e) A partition segments in the Bipartite version.

Splitting (Lemma 2.6.1 [19, 31]) is used throughout this dissertation for inductive arguments. Some important examples of splitting follow.

- If a line $\ell$ does not cross any segment of a finite multiset of segment $S$, then the partition $S=S_{0} \cup S_{1} \cup S_{2}$ where $S_{0}$ are the segments of $S$ which lie are contained in $\ell$, where $S_{1}$ are the segments of $S$ which lie on one side of $\ell$, and where $S_{2}$ are the segments of $S$ which lie on the other side of $\ell$ splits $S$. In this case, we say that $\ell$ splits $S$ (Figure 2.2(a)).

[^9]- More generally, if there exists a decomposition $P=\bigcup_{i=1}^{k} P_{i}$ of the point set $P$ induced by a partition $S=\bigcup_{i=1}^{k} S_{i}$ of the multiset of segments $S$ such that the convex hulls of the $P_{i}$ have pairwise disjoint interiors, then the partition splits $S$. In this case, we say that the splitting is convex (Figure 2.2(b)).
- In particular, in such a convex splitting, some of the convex hulls may consist of only one segment, as it is the case if $S$ is crossing free (Figure 2.2(c)).
- However, some splitting partitions are not convex; Figure 2.2(d) shows a multiset of segments $S$ and a segment $s \in S$ such that the partition $\{s\} \cup S \backslash\{s\}$ splits $S$ while not being convex.
- If a singleton $\{s\}$ is one of the partitions in a splitting partition, then we say that the segment $s$ is uncrossable (the segment $s$ is uncrossable in Figure 2.2(a) and Figure 2.2(d), and also all the three segments of Figure 2.2(c)). ${ }^{3}$

[^10]
## Chapter 3

## Literature Review

In this chapter, we present the results from the literature falling in problematic of this dissertation, namely from [17, 19, 72, 82, 85]. We omit the proof of Theorem 3.2.9 and give only a structure for the proofs of Theorem 3.2.4 and Theorem 3.1.5. We adapt and generalize the presentation of the rest of the proofs. First, we give a short review of each of these five articles.

Untangling a Traveling Salesman Tour in the Plane by Jan Van Leeuwen and Anneke A. Schoone in 1980 [82, 83] This article ${ }^{1}$ is the seminal work of all the following articles and of the present dissertation. First, they provide a formal proof of the folklore theorem which asserts that the shortest tours have no self intersection if the cities are not all colinear. Last but not least, they prove that any untangle sequence is of length at most $n^{3}$ ( $n$ being the number of segments in the tours), more formally that:

- $\mathbf{d}_{\text {Cycle }}^{\emptyset}(n) \leq n^{3}$ (Theorem 3.1.3).

This proof is written for the Cycle version (and do not assume general position for the point set) but it is straightforward to adapt to the Matching version $[19]^{2}$, or to generalize it to the Multigraph version (we present this generalisation in Theorem 3.1.3). In this proof, they introduce a potential function (the function mapping a tour to the number of intersections between a set of lines and the set of segments of the tour). This idea is at the core of many results in $[17,19,30,31,33]$ and therefore in the present dissertation.

The Number of Flips Required to Obtain Non-crossing Convex Cycles by Yoshiaki Oda and Mamoru Watanabe in 2007 [72]. This article provides the following upper and lower bounds:

- $\mathrm{d}_{\text {Convex Cycle }}^{\mathrm{R}}(n) \leq 2 n-7$ for $n \geq 4$ (Theorem 3.2.7),
- $n-2 \leq \mathbf{d}_{\text {Convex Cycle }}^{\mathrm{R}}(n)$ for $n=5$ and for $n \geq 7$.

[^11]The article also studies $\mathbf{d}_{\text {Convex }}^{\mathrm{R}}$ Cycle restricted to some specific classes of convex polygons. The last section conjectures that $\mathbf{d}_{\text {Convex Cycle }}^{\mathrm{R}}(n)=n-2$ for $n \geq 7$, then computationally checks this conjecture for $7 \leq n \leq 11$. A list of convex polygons satisfying the conjecture is also provided.

On the Maximum Switching Number to Obtain Non-crossing Convex Cycles by Ro-Yu Wu, Jou-Ming Chang, and Jia-Huei Lin in 2009 [85]. This article proves the conjecture of [72], namely:

- $\mathrm{d}_{\text {Convex Cycle }}^{\mathrm{R}}(n) \leq n-2$ for $n \geq 7$ (Theorem 3.2.9).

Flip Distance to a Non-crossing Perfect Matching by Édouard Bonnet and Tillmann Miltzow in 2016 [19]. This article proves the following bounds:

- $\mathbf{d}_{\text {Matching }}^{\emptyset}(n) \leq n^{3}$ (Theorem 3.1.3),
- $\binom{n}{2} \leq \mathbf{d}_{\text {Convex Permutation Matching }}^{\natural}(n)$ (Theorem 3.2.1),
- $n-1 \leq \mathbf{d}_{\text {Convex Matching }}^{\mathrm{RI}}(n)$ (Theorem 3.2.12),
- $\mathbf{d}_{\text {Matching }}^{\mathrm{T}}(n) \leq \frac{n^{2}}{2}$ (Theorem 3.1.4).

The proof provided for the third bound is in fact a proof of the following stronger result: $n-1 \leq \mathbf{d}_{\text {Matching }}^{\mathrm{RI}}(n)$. The article additionally contains the following conjecture: $\mathbf{d}_{\text {Matching }}^{\emptyset}=O\left(n^{2}\right)$, which we generalize to the Multigraph version in Conjecture 1. This conjecture remains open.

Flip Distance to some Plane Configurations by Ahmad Biniaz, Anil Maheshwari, and Michiel Smid in 2019 [17]. This article is the most recent of the five. The following bounds are proven:

- $\mathbf{d}_{\text {Matching }}^{\mathrm{T}}(n)=O(n \sigma(P)) \quad$ where $\sigma(P)$ is the spread of the point set $P$ (Theorem 3.1.5),
- $\mathbf{d}_{\text {Convex Matching }}^{\natural}(n) \leq\binom{ n}{2}$ (Theorem 3.2.2),
- $\mathbf{d}_{\text {Convex Matching }}^{\mathrm{RI}}(n) \leq n-1$ (Theorem 3.2.13),
- $\mathbf{d}_{\text {Convex Bipartite Matching }}^{\mathrm{R}}(n) \leq 2 n-2$ (Theorem 3.2.10),
- $\left.\mathbf{d}_{\text {Convex }}^{\mathrm{R}} \mathrm{Tree}^{( } n\right)=O(n \log n)$ (Theorem 3.2.11),
- $\mathrm{d}_{\text {Redonaline Matching }}^{\mathrm{R}}(n) \leq n(n-1)$ (Theorem 3.3.1).

The proofs of the two first bounds in fact holds for the Convex Multigraph version. The proofs in [17] of second and the third bounds are both very similar to the proof of the upper bound on $\mathbf{d}_{\text {Convex Cycle }}^{\mathrm{R}}$ in [72], and all use the same notion of depth of a segment. We present proofs based on a similar but distinct notion, which we call the crossing depth of a segment.

### 3.1 General Point Sets

In this section, we prove the literature results concerning general point sets.

### 3.1.1 Untangling with No Choice

In this section, we prove the only literature bound on tho length of untangle sequences with no choice: the unchallenged 1980 cubic upper bound on $\mathbf{d}_{\text {Multigraph }}^{\natural}$. The literature contains no lower bound specific to untangle sequences with no choice, the best lower bound known on $\mathbf{d}_{\Pi}^{\varphi}$ for any $\Pi$ is discussed next.

## Lower Bound

To our knowledge, the longest untangle sequences contained in the literature are all with point sets in convex position and their length is $\Theta\left(n^{2}\right)$ (Theorem 3.2.1). This could lead to conjecture that some of the longest untangle sequences are indeed attained with point sets in convex position. We disprove this conjecture in Theorem 4.2.1. However, the following conjecture, formulated for the Matching version in [19], is not disproved and matches our current belief.

Conjecture 1 ([19]). In the Multigraph version, any untangle sequence is of length at most $O\left(n^{2}\right)$.

In other words, we have the following upper bound: $\mathbf{d}_{\text {Multigraph }}^{\natural}=O\left(n^{2}\right)$.

## Upper Bound

In the 1980 technical report [82] and the year after in the workshop [83], Jan van Leeuwen and Anneke A. Schoone proved Theorem 3.1.3 in the Cycle version. It is the seminal result of the present dissertation. An adaptation of the proof to the Bipartite Matching version has been presented in [19]. We present here a generalization to the Multigraph version.

It is notable that, in [82], general position is not assumed. In the following, we also present the proof of Theorem 3.1.3 without any assumption on the point set. This leads to consider a generalization of flips defined as follows. A general fip in the $\Pi$ version is an operation removing two intersecting segments from a multiset of segments and inserting two non-intersecting segments with the same four endpoints while preserving a property $\Pi$ of the multiset of segments. In this setting, segments degenerated to a point are allowed; they are modeled by loops in the corresponding multigraph. There are seven types of general flips depending on the type of intersection of the removed segments (Figure 3.1).

- Type I: the removed segments are crossing (the general flips of type I are the flips).
- Type $I I$ : the removed segments intersect at exactly one point which is one of the endpoints of exactly one of the removed segments.
- Type III: the removed segments intersect at exactly one point which is one of the endpoints of both removed segments.
- Type $I V$ : the removed segments intersect at infinitely many points, their four endpoints are distinct, and one removed segment contains the other.
- Type $V$ : the removed segments intersect at infinitely many points, their four endpoints are distinct, and none of the removed segments contains the other.
- Type VI: the removed segments intersect at infinitely many points, and they share exactly one endpoint.
- Type VII: the removed segments intersect at infinitely many points, and their are identical.

Note that in the general flips of type III to VII, the insertion choice is set by the condition that the inserted segments do not intersect. If, for a given pair of segments, this insertion choice does not preserves the property $\Pi$, then the pair of segments cannot be flipped.

We prove Theorem 3.1.3 using Lemma 3.1.1 and Lemma 3.1.2 which we state and prove next. Lemma 3.1.1 relies on a third elementary lemma (Lemma 2.4.1). The following definitions are used.

We define $\Lambda_{\ell}(S)$ as the number of segments of the multiset $S$ crossing the line $\ell$ (counted with their multiplicity). If $L$ is a set (or a multiset) of lines, we define $\Lambda_{L}(S)$ as the sum of the $\Lambda_{\ell}(S)$ for $\ell \in L$.

Lemma 3.1.1. Consider a line $\ell$ and a multiset of segments $S$. A general fip of $S$ does not increase $\Lambda_{\ell}(S)$.

Proof. Let $p_{1} p_{2}$ and $p_{3} p_{4}$ be the two segments removed by the general flip, let $o$ be one of their intersection points, and let $p_{1} p_{3}$ and $p_{2} p_{4}$ be the two segments inserted by the general flip. We show that any crossing pair consisting of $\ell$ and an inserted segment is reflected by a crossing pair consisting of $\ell$ and a removed segment.

If both removed segments cross $\ell$, or if none of the inserted segments cross $\ell$, then the lemma holds. The only remaining case is when $\ell$ crosses only one inserted segment, say $p_{1} p_{3}$. Then, $\ell$ intersects the (possibly flat) triangle $p_{1} p_{3} o$. Thus by the triangle argument (Lemma 2.4.1), $\ell$ also intersects $p_{1} o \cup p_{3} O$ at exactly one point $o^{\prime}$ (which is not $p_{1}$ or $p_{3}$ ). This intersection $o^{\prime}$ is not $o$ either, as we have assumed that at least one of the removed segments does not cross $\ell$. Therefore, $o^{\prime}$ is not $p_{2}$ or $p_{4}$ and the lemma holds.

Before we state and prove Lemma 3.1.2, we need the following additional definitions. Given two distinct points $p_{1}, p_{2}$ of a point set $P$, let $p_{1} p_{2}^{+}$and $p_{1} p_{2}^{-}$by two lines crossing the segment $p_{1} p_{2}$ and being as close to the line $p_{1} p_{2}$ as necessary to satisfy the following properties for all segments $s$ with endpoints in $P^{3}$.

- If the endpoints of $s$ do not lie on the line $p_{1} p_{2}$, then $p_{1} p_{2}^{+}$(respectively $p_{1} p_{2}^{-}$) intersects $s$ if and only if the line $p_{1} p_{2}$ intersects $s$.
- If exactly one of the endpoints of $s$ lies on the line $p_{1} p_{2}$, then exactly one of $p_{1} p_{2}^{+}$ or $p_{1} p_{2}^{-}$intersects $s$.

[^12]In other words, the two partitions of $P \backslash p_{1} p_{2}$ induced by the lines $p_{1} p_{2}^{+}$and $p_{1} p_{2}^{-}$are the same as the partition induced by $p_{1} p_{2}$ and are different from each other. We say that $p_{1} p_{2}^{+}$and $p_{1} p_{2}^{-}$are the witnesses of the segment $p_{1} p_{2}$. Let $L$ be the multiset of the lines $p_{1} p_{2}^{+}$and $p_{1} p_{2}^{-}$for all pairs of points $p_{1}, p_{2} \in P^{4}$.

(I)

(II)

(III)

(IV)
(V)

(VI)

(VII)

Figure 3.1: The seven types of general flips (removed segments are plain bold, inserted segments are dashed) with the two witness lines (doted and highlighted) in $L$ decreasing $\Lambda_{\ell}$.

Lemma 3.1.2. For any general flip, there exists at least two lines $\ell \in L$ such that $\Lambda_{\ell}$ decreases by 2.

Proof. An exhaustive case analysis of the seven types of general flips yields that each removed segment has a witness $\ell \in L$ such that $\Lambda_{\ell}$ decreases by 2 (Figure 3.1).

Theorem 3.1.3 ([19, 82]). Consider a multiset $S$ of $n$ segments with endpoints $P$.
In the Multigraph version, any untangle sequence of $S$ is of length at most $\frac{1}{2} n\binom{P|P|}{2}=$ $O\left(n|P|^{2}\right)=O\left(n^{3}\right)$.

In other words, we have the following upper bound:

$$
\mathbf{d}_{\text {Multigraph }}^{\emptyset}(n) \leq \frac{1}{2} n\binom{|P|}{2}=O\left(n|P|^{2}\right)=O\left(n^{3}\right) .
$$

Proof. A consequence of Lemma 3.1.1 and Lemma 3.1.2 is that $\Lambda_{\ell}$ decreases by at least 4 at each general flip. Moreover, each of the $2\binom{|P|}{2}$ lines in $L$ crosses at most $n$ segments. Thus, the function $\Lambda_{\ell}$ takes integer values between 0 and $2 n\binom{|P|}{2}$, hence the theorem.

### 3.1.2 Untangling with Insertion Choice

In this section, we present the two upper bounds on $\mathbf{d}_{\text {Multigraph }}^{\mathrm{I}}$ from the literature: a general upper bound and an upper bound parameterized by the spread of the point set (defined next). These results do not carry over to the Cycle version where insertions are set to preserve the Cycle property.

The literature contains no lower bound specific to insertion choice, the best lower bound known on $\mathbf{d}^{\mathrm{I}}$ is a corollary of Theorem 3.2.12.

[^13]
## General Upper Bound

The following theorem provides a quadratic upper bound and relies on insertion choice. We extend our standard general position assumptions to also exclude pairs of endpoints with the same $y$-coordinate.

Theorem 3.1.4 ([19]). Consider a multiset $S$ of $n$ segments with endpoints $P$.
In the Multigraph version, there exists an insertion strategy such that for any removal strategy, the resulting untangle sequence of $S$ is of length at most $\frac{n}{2}(|P|-2)=$ $O(n|P|)=O\left(n^{2}\right)$.

In other words, we have the following upper bound:

$$
\mathbf{d}_{\text {Multigraph }}^{\mathrm{I}}(n) \leq \frac{n}{2}(|P|-2)=O(n|P|)=O\left(n^{2}\right) .
$$

Proof. Let $p_{1}, \ldots, p_{|P|}$ be the points of $P$ sorted vertically from top to bottom. Consider a flip involving the points $p_{a}, p_{b}, p_{c}, p_{d}$ with $a<b<c<d$. There are two cases whether the removed pair of segments is $p_{a} p_{c}, p_{b} p_{d}$ or $p_{a} p_{d}, p_{b} p_{c}$. In both cases, we choose to insert the pair of segments $p_{a} p_{b}, p_{c} p_{d}$.

We now prove that this insertion choice leads to the claimed upper bound. We define the potential $\eta$ of a segment $p_{i} p_{j}$ as $\eta\left(p_{i} p_{j}\right)=|i-j|$. Notice that $\eta$ is an integer between 1 and $|P|-1$. We define $\eta(S)$ as the sum of $\eta\left(p_{i} p_{j}\right)$ for $p_{i} p_{j} \in S$. The function $\eta$ is equal to $\Lambda_{L}$ where $L$ is a set of $|P|-1$ horizontal lines that partition the plane with one point of $P$ per partition.

Notice that $n \leq \eta(S) \leq n(|P|-1)$. It is easy to verify that, in both cases for the removed pair of segments, a flip decreases $\eta(S)$ by at least 2 . Hence, the number of flips is $\frac{n}{2}(|P|-2)=O(n|P|)$.

## Parameterized Upper Bound

Next, we state Theorem 3.1.5; the statement is identical to Theorem 3.1.4 except that the upper bound is $O(n \sigma(P))$ instead of $O\left(n^{2}\right)$. This calls for the following definition. If $P$ is a set of points, let $\sigma(P)$ be the spread of the point set $P$, that is, the ratio between the maximum and minimum distances among pairs of points in $P$.

Note that the spread $\sigma(P)$ is not invariant by affine transformation, and thus is not an invariant of the problem. Recall that the problem of untangling a multigraph only depends on the the order type of the point set ${ }^{5}$. Therefore, Theorem 3.1.5 still holds when replacing $\sigma(P)$ by the minimum of $\sigma\left(P^{\prime}\right) P^{\prime}$ varies over all the point sets of the same order type as $P$.

Also note that Theorem 3.1.5 improves on Theorem 3.1.4 only when $\sigma(P)=o(n)$. As the spread $\sigma(P)$ of a point set $P$ is always lower bounded by $\Omega(\sqrt{n})$ (see e.g., [79]), the best improvement is attained for dense point sets $P$, where $\sigma(P)=\Theta(\sqrt{n})$. Dense point sets appear in practical situations and have been studied in several contexts (see e.g., [39]).

[^14]Theorem 3.1.5 ([17]). Consider a multiset $S$ of $n$ segments with endpoints $P$.
In the Multigraph version, there exists an insertion strategy such that for any removal strategy, the resulting untangle sequence of $S$ is of length $O(n \sigma(P))$.

In other words, we have the following upper bound:

$$
\mathbf{d}_{\text {Multigraph }}^{\mathrm{I}}(n)=O(n \sigma(P)) .
$$

The proof of Theorem 3.1.5 relies on Lemma 3.1.8, itself relying on Lemma 3.1.6 and Lemma 3.1.7. As the three lemmas are only technical lemmas, we only prove Theorem 3.1.5 assuming Lemma 3.1.8.

Lemma 3.1.6 ([17]). Let $p_{1} p_{2}$ and $p_{3} p_{4}$ be two crossing segments. Let o be their crossing point. Let $\mu$ be the minimum distance between any pair of points in $\left\{p_{1}, p_{2}, p_{3}, p_{4}\right\}$. If the angle $\angle p_{3} O p_{2} \leq \frac{\pi}{3}$, then $\mu \leq\left(p_{1} p_{2}+p_{3} p_{4}\right)-\left(p_{2} p_{4}+p_{3} p_{2}\right)$.

Lemma 3.1.7 ([17]). Let $p_{1} p_{2}$ and $p_{3} p_{4}$ be two crossing segments. Let o be their crossing point. Let $\mu$ be the minimum distance between any pair of points in $\left\{p_{1}, p_{2}, p_{3}, p_{4}\right\}$. If the angle $\angle p_{3} o p_{2}=\frac{\pi}{2}$, then $\frac{2-\sqrt{2}}{2} \mu \leq\left(p_{1} p_{2}+p_{3} p_{4}\right)-\left(p_{2} p_{4}+p_{3} p_{2}\right)$.

Lemma 3.1.8 ([17]). Let $p_{1} p_{2}$ and $p_{3} p_{4}$ be two crossing segments. Let o be their crossing point. Let $\mu$ be the minimum distance between any pair of points in $\left\{p_{1}, p_{2}, p_{3}, p_{4}\right\}$. If the angle $\angle p_{3} o p_{2} \leq \frac{\pi}{2}$, then $\frac{2-\sqrt{2}}{4} \mu \leq\left(p_{1} p_{2}+p_{3} p_{4}\right)-\left(p_{2} p_{4}+p_{3} p_{2}\right)$. In other words, inserting the pair of segments facing the two smallest angles among the four angles defined by the removed segments decreases the total length by at least $\frac{2-\sqrt{2}}{4} \mu$ (the constant $\frac{2-\sqrt{2}}{4}$ is not optimized).

The idea of the proof of Theorem 3.1.5 is to use insertion choice to systematically insert a pair of segments such that the sum of the lengths of all the segments in $S$ decreases by a constant factor.

Proof of Theorem 3.1.5. Let $\mu(P)$ be the minimal distance between two points of $P$. Let $\Gamma(S)$ be the sum of the lengths of all the segments in $S$. We have $\Gamma(S)=O(n \mu(P) \sigma(P))$. We systematically insert the pair of segments facing the two smallest angles among the four angles defined by the removed segments. By Lemma 3.1.8, this insertion strategy decreases $\Gamma(S)$ by at least $\frac{2-\sqrt{2}}{4} \mu(P)$, yielding Theorem 3.1.5.

### 3.2 Convex Position Point Sets

In this section, we prove the literature results concerning point sets in convex position. In this convex case, the geometry of the point set is fully encoded by the cyclic order of the points on the convex hull boundary, leading to fully combinatorial proofs.

### 3.2.1 Untangling with No Choice

In this section, we prove that $\binom{n}{2}$ is both a lower bound on $\mathbf{d}_{\text {Convex Permutation Matching }}^{\natural}$ and an upper bound on $\mathbf{d}_{\text {Convex }}^{\emptyset}$ Multigraph .

These two bounds together lead to the following identities.

```
\(\forall \Pi \in\{\) Multigraph,
    Bipartite Multigraph,
    Matching,
    Bipartite Matching,
    Redonaline Matching,
    Permutation Matching \(\} \quad \mathbf{d}_{\text {Convex } \Pi}^{\emptyset}(n)=\binom{n}{2}\)
```

Note that the proof of the lower bound (Theorem 3.2.1) presented next does not hold in the Cycle version or in the Tree version. However, the reductions presented in Theorem 4.1.1 extend this lower bound asymptotically, yielding $\mathbf{d}_{\text {Convex } \Pi}^{\emptyset}=\Theta\left(n^{2}\right)$ for $\Pi \in\{$ Cycle, Tree $\}$.

## Lower Bound

In this section, we prove the following lower bound.
Theorem 3.2.1 ([19]). There exists a set $S$ of $n$ segments forming a bipartite matching with red points on a line $\ell_{1}$ and blue points on a line $\ell_{2}$ parallel to $\ell_{1}$ such that there exist (in the Convex Permutation Matching version) an untangle sequence of $S$ of length $\binom{n}{2}$.

In other words, we have the following lower bound:

$$
\mathbf{d}_{\text {Convex Permutation Matching }}^{\emptyset}(n) \geq\binom{ n}{2}=\Omega\left(n^{2}\right)
$$

Figure 3.2: A lower-bounding bubble sort untangle sequence used in the proof of Theorem 3.2.1.

Proof. Let $R=\left\{r_{1}, \ldots, r_{n}\right\}$ be a set of $n$ red points. Let $B=\left\{b_{1}, \ldots, b_{n}\right\}$ be a set of $n$ blue points. There exists a canonical bijection between $\mathfrak{S}_{n}$, the permutations of $\{1, \ldots, n\}$, and the bipartite matchings on $R, B$.

Moreover, if the red and blue points are on the boundary of a convex body, the red points being on one side of a horizontal line and the blue points being on the other side, with red and blue points order from left to right, then the only crossing-free bipartite matching on $R, B$ corresponds to the identity in $\mathfrak{S}_{n}$, and the crossing pairs of segments in a matching corresponds to the inversions. This hypothesis is satisfied as the red points lie on a line $\ell_{1}$ and the blue points lie on a line $\ell_{2}$ parallel to $\ell_{1}$.

Therefore, a bubble sort of the permutation mapping any $i \in\{1, \ldots, n\}$ to $n+1-i$ corresponds to an untangle sequence with $\binom{n}{2}$ flips (Figure 3.2)).

## Upper Bound

In this section, we prove the following upper bound.
Theorem 3.2.2 ([17]). Consider a multiset $S$ of $n$ segments with endpoints $P$ in convex position and with $m$ crossing pairs of segments. In the Convex Multigraph version, all untangle sequences of $S$ have length at most $m$.

In other words, we have the following upper bound:

$$
\mathbf{d}_{\text {Convex Multigraph }}^{\emptyset}(n) \leq\binom{ n}{2}=O\left(n^{2}\right) .
$$

Figure 3.3: The five convex positions of $s$ with respect to the removed and inserted pairs. This is used in the proof of Lemma 3.2.3.

Lemma 3.2.3. Consider three segments with endpoints in convex position. In the Convex Multigraph version, flipping two segments does not increase the number of crossing pairs involving the third segment.

The proof we present hereafter is syntactically identical to the proof of Theorem 3.1.3 (up to replacing the line $\ell$ by the segment $s$ ) which uses a triangle argument (Lemma 2.4.1). The triangle argument normally applies to a line, but a segment behaves like a line if it is long enough, which is the case with a convex point set. In fact, the triangle argument with a long segment instead of a line translates into a combinatorial argument if the endpoints involved are in convex position.

Note that Lemma 3.2.3 also admits a proof by exhaustive case analysis as shown in Figure 3.3. Not only is this exhaustion informative, but it is also used in the proof of Lemma 5.1.4.

Proof of Lemma 3.2.3. Let $p_{1} p_{2}$ and $p_{3} p_{4}$ be the two segments removed by the flip, let $o$ be their intersection point, and let $p_{1} p_{3}$ and $p_{2} p_{4}$ be the two segments inserted by the flip. Let $s$ be the third segment. We show that any crossing pair involving $s$ and an inserted segment is reflected by a crossing pair involving $s$ and a removed segment.

If both removed segments cross $s$, or if none of the inserted segments cross $s$, then the lemma holds. The only remaining case is when $s$ crosses only one inserted segment, say $p_{1} p_{3}$. Then, $s$ intersects the (possibly flat) triangle $p_{1} p_{3} o$. Thus by the triangle argument (Lemma 2.4.1), $s$ also intersects $p_{1} o \cup p_{3} O$ at exactly one point $o^{\prime}$ (which is not $p_{1}$ or $p_{3}$ ). This intersection $o^{\prime}$ is not $o$ either, as we have assumed that at least one of the removed segments does not cross $s$. Therefore, $o^{\prime}$ is not $p_{2}$ or $p_{4}$ and the lemma holds.

(a)

(b)

(c)

Figure 3.4: (a) A polygon maximizing the number of crossing pairs of segments with an odd number of segments. (b) A polygon maximizing the number of crossing pairs of segments with an even number of segments. (c) A tree maximizing the number of crossing pairs of segments.

Proof of Theorem 3.2.2. Let $\chi(S)$ be the number of crossing pairs of segments of $S$. Notice that $\chi(S)$ takes integer values between 0 and $\binom{n}{2}$. Lemma 3.2.3 ensures that $\chi$ decreases by at least 1 at a flip; Theorem 3.2.2 follows.

Note that this upper bound can be refined in the Convex Cycle version using the fact that the maximum number of crossing pair of segments in a polygon with $n$ segments is $\binom{n}{2}-n$ if $n$ is odd and $\binom{n}{2}-\frac{3}{2} n+1$ if $n$ is even [46]. The case where $n$ is odd is attained with a polygon where each segment crosses all the other segments except its neighbors (Figure 3.4(a)). The case where $n$ is even is less obvious (Figure 3.4(b)). Similarly, in the Convex Tree version, the maximum number of crossings $\binom{n}{2}-n+1$ is attained for a path where each segment crosses all the other segments except its neighbors (Figure 3.4(c)).

### 3.2.2 Untangling with Removal Choice

In this section, we prove linear lower and upper bounds on $\mathbf{d}_{\text {Convex }}^{\mathrm{R}}$ cycle (settling even the exact value) and an $O(n \log n)$ upper bound on $\mathbf{d}_{\text {Convex } \operatorname{Tree}}^{\mathrm{R}}(n)$ from the literature.

## Lower Bound

In this section, we prove the following lower bound.
Theorem 3.2.4 ([72]). There exists polygons with $n$ segments and endpoints in convex position such that (in the Convex Cycle version) any untangle sequence is of length at least $n-3$ if $n \in\{3,4,6\}$ and at least $n-2=\Omega(n)$ if $n=5$ or $n \geq 7$.

In other words, we have the following lower bound:

$$
\mathbf{d}_{\text {Convex Cycle }}^{\mathrm{R}}(n) \geq \begin{cases}n-3 & \text { for } n \in\{3,4,6\} \\ n-2=\Omega(n) & \text { for } n=5 \text { and } n \geq 7\end{cases}
$$

The proof of relies on the next two lemmas whose statement use the following definitions. The proofs of these two lemmas are omitted.

For odd $n$, we define $\mathcal{C}_{n, 2}$ as the polygon on $n$ points in convex position with edges defining a cycle skipping every other point in cyclic order on the convex hull.

For even $n$, we define $\mathcal{D}_{n}$ as the polygon on $n$ points in convex position with edges defining the following cycle described with the indices of the points sorted in counterclockwise order on the convex hull.

$$
(1,3,5, \ldots, n-5, n-2, n, n-3, n-1,2,4,6, \ldots, n-4)
$$

Lemma 3.2.5. Let $n$ be a positive odd integer at least 5. In the Convex Cycle version, any untangle sequence of the polygon $\mathcal{C}_{n, 2}$ is of length at least $n-2$.

Lemma 3.2.6. Let $n$ be a positive even integer at least 8. In the Convex Cycle version, any untangle sequence of the polygon $\mathcal{D}_{n}$ is of length at least $n-2$.

We now provide a short proof of Theorem 3.2.4 assuming Lemma 3.2.5 and Lemma 3.2.6.

Proof of Theorem 3.2.4. It is easy to check that $\mathbf{d}_{\text {Convex Cycle }}^{\mathrm{R}}(3)=0, \mathbf{d}_{\text {Convex Cycle }}^{\mathrm{R}}(4)=1$, $\mathbf{d}_{\text {Convex Cycle }}^{\mathrm{R}}(5)=3$, and $\mathbf{d}_{\text {Convex Cycle }}^{\mathrm{R}}(6)=3$. Lemma 3.2.5 and Lemma 3.2.6 yield Theorem 3.2.4 for $n \geq 7$.

## Upper Bounds

In this section, first we define the crossing depth (used in the proofs of Theorem 3.2.7, Theorem 3.2.10, Theorem 3.2.13, and Theorem 5.2.1) of a segment. All the proofs using these definition are very similar.

Then, we state four theorems providing linear or quasilinear upper bounds on $\mathrm{d}_{\text {Convex }}^{\mathrm{R}}$ : two for the Cycle version, one for the Bipartite Matching version, and one for the Tree version. We provide proofs for only two of them. We omit the proof of Theorem 3.2.9 which improves the constants of the upper bound of Theorem 3.2.7 to reach exact tightness. We delay the proof of Theorem 3.2.11 to the proof of the more general Theorem 5.2.1.

Crossing depth. Consider a multiset $S$ of $n$ segments with endpoints $P$ in convex position. Let $p_{1}, \ldots, p_{|P|}$ be the points of $P$ sorted in counterclockwise order along the convex hull boundary. Consider a segment $p_{a} p_{b}$, assuming without loss of generality that $a<b$.

We define the crossing depth $[31]^{6} \delta_{\times}\left(p_{a} p_{b}\right)$ as the number of points in $p_{a+1}, \ldots, p_{b-1}$ that are an endpoint of a segment in $S$ that crosses any segment in $S$ (not necessarily $p_{a} p_{b}$ ).

Note that the crossing depth of a segment is a non-negative integer at most $|P|-2$. Also note that, by splitting (Lemma 2.6.1 [19, 31]), the segments of crossing depth 0 are uncrossable and can no longer participate in a flip.

The following theorem provides a linear upper bound in the Convex Cycle version.

[^15]Theorem 3.2.7 ([72]). Any polygon $S$ with $n$ segments and endpoints $P$ in convex position admits (in the Convex Cycle version) an untangle sequence of length at most $2 n-7=O(n)$ for $n \geq 4$.

In other words, we have the following upper bound:

$$
\mathbf{d}_{\text {Convex Cycle }}^{\mathrm{R}}(n) \leq 2 n-7=O(n) \text { for } n \geq 4
$$

The proof of Theorem 3.2.7 relies on the following lemma.
Lemma 3.2.8 ([72]). Any polygon $S$ with $n$ segments and endpoints $P$ in convex position admits an uncrossable segment $s \in S$ after at most 1 flip (in the Convex Cycle version).

Proof. Note that, in the case of polygons with endpoints in convex position, the uncrossable segments are the segments contained in the boundary of the convex hull of $P$ which are the segments of null crossing depth. We assume that $S$ contains no uncrossable segment. Let $p_{1}, \ldots, p_{|P|}$ be the points of $P$ sorted in counterclockwise order along the convex hull boundary.

Let $p_{a} p_{b} \in S(a<b)$ be a segment with crossings (hence, of crossing depth at least one) minimizing $\delta_{\times}\left(p_{a} p_{b}\right)$. Let $q_{1}, \ldots, q_{\delta_{\times}\left(p_{a} p_{b}\right)}$ be the points defining $\delta_{\times}\left(p_{a} p_{b}\right)$ sorted in counterclockwise order along the convex hull boundary.

Since $p_{a} p_{b}$ has minimum positive crossing depth, and since we assume that $S$ contains no uncrossable segment, the point $q_{1}$ is the endpoint of two segments $s, s^{\prime}$, each of them either crossing $p_{a} p_{b}$. It is easy to see that, by definition of a flip in the Cycle version, flipping one of these two segments, say $s$, with the segment $p_{a} p_{b}$ inserts the segment $q_{1} p_{a}$ while flipping $s^{\prime}$ with the segment $p_{a} p_{b}$ does not insert the segment $q_{1} p_{a}$. We choose to remove the segments $s$ and $p_{a} p_{b}$, because, being of null crossing depth, the inserted segment $q_{1} p_{a}$ is uncrossable.

Proof of Theorem 3.2.7. We now prove Theorem 3.2.7 by induction on $n$.
If $n=4$, then $\mathbf{d}_{\text {Convex Cycle }}^{\mathrm{R}}(n)=1$.
If $n \geq 5$, and if $\mathbf{d}_{\text {Convex Cycle }}^{\mathrm{R}}(n-1) \leq 2(n-1)-7$, then, by Lemma 3.2.8, using at most 1 flip ensures that there exists at least one uncrossable segment $s$ in $S$. We invoke the induction hypothesis on the polygon with $n-1$ segments obtained from $S$ by contracting the segment $s$ to a point. The resulting flip sequence also transforms $S$ into a polygon where only the two segments adjacent to $s$ may cross. A final flip is enough to fully untangle $S$. The total number of flips use to untangle $S$ is at most $2+2(n-1)-7=2 n-7$, concluding the induction.

The following theorem refines Theorem 3.2.7 with a tight bound.
Theorem 3.2.9 ([85]). Any polygon with $n \geq 7$ segments and endpoints in convex position admits (in the Convex Cycle version) an untangle sequence of length at most $n-2=O(n)$.

In other words, we have the following upper bound:

$$
\mathbf{d}_{\text {Convex Cycle }}^{\mathrm{R}}(n) \leq n-2=O(n) \quad \text { for } n \geq 7
$$

The article [85] is entirely dedicated to the proof of Theorem 3.2.9; we omit this proof here.

The following theorem also provides a linear upper bound, but in the Convex Bipartite Matching version. ${ }^{7}$

Theorem 3.2.10 ([17]). Consider a set $S$ of $n$ segments with endpoints $P$ in convex position partitioned into $n$ red points and $n$ blue points such that $(P, S)$ forms a bipartite matching.

In the Convex Bipartite Matching version, there exists an untangle sequence of $S$ of length at most $2 n-3=O(n)$.

In other words, we have the following upper bound:

$$
\mathrm{d}_{\text {Convex Bipartite Matching }}^{\mathrm{R}}(n) \leq 2 n-3=O(n) .
$$

To prove Theorem 3.2.10, we use removal choice to iteratively remove a segment of minimal positive crossing depth and insert a segment of null collapsed crossing depth using two flips.

Proof of Theorem 3.2.10. Consider a multiset $S$ of $n$ segments with endpoints $P$ in convex position. Let $p_{1}, \ldots, p_{|P|}$ be the points of $P$ sorted in counterclockwise order along the convex hull boundary.

We repeat the following procedure until there are no more crossings. Let $p_{a} p_{b} \in S$ $(a<b)$ be a segment with crossings (hence, of crossing depth at least one) minimizing $\delta_{\times}\left(p_{a} p_{b}\right)$. Without loss of generality, assume that $p_{a}$ is red and that $p_{b}$ is blue. Let $q_{1}, \ldots, q_{\delta_{\times}\left(p_{a} p_{b}\right)}$ be the points defining $\delta_{\times}\left(p_{a} p_{b}\right)$ sorted in counterclockwise order along the convex hull boundary.

We have the following two cases.

Case 1: using one flip. In Case $1, q_{1}$ is blue or $q_{\delta_{\times}\left(p_{a} p_{b}\right)}$ is red. We assume without loss of generality that $q_{1}$ is red. Since $p_{a} p_{b}$ has minimum positive crossing depth, the point $q_{1}$ is the endpoint of a segment $q_{1} p_{c} \in S$ that crosses $p_{a} p_{b}$. In this case, we chose to remove the segments $q_{1} p_{c}$ and $p_{a} p_{b}$. By definition of $q_{1}$, the crossing depth of the inserted segment $q_{1} p_{a}$ is 0 .

Case 2: using two flips. In Case 2, $q_{1}$ is red and $q_{\delta_{\times}\left(p_{a} p_{b}\right)}$ is blue. Let $i$ be the smallest index such that $q_{i}$ is blue. Thus, $q_{i-1}$ is red. Again, since $p_{a} p_{b}$ has minimum positive crossing depth, the point $q_{i-1}$ is the endpoint of a segment $q_{i-1} p_{c} \in S$ that crosses $p_{a} p_{b}$. We chose to remove the segments $q_{i-1} p_{c}$ and $p_{a} p_{b}$. The inserted segments are $q_{i-1} p_{b}$ and $p_{a} p_{c}$.

At this point, the segment $q_{i-1} p_{b}$ crosses a segment $q_{i} p_{d}$ incident to $q_{i}$ (in fact, any such segment). We chose to remove these two segments, i.e., $q_{i-1} p_{b}$ and $q_{i} p_{d}$. The inserted segments are $q_{i-1} p_{b}$ and $p_{a} p_{c}$. The crossing depth of the inserted segment $q_{i} q_{i-1}$ is 0 , by definition of $i$.

In both cases, we have used at most 2 flips to remove segments with positive crossing depths and insert at least one segment with null crossing depth. Thus, the number of segments with positive crossing depth decreases by at least 1 every two flips. Using

[^16]at most $2(n-2)$ flips is enough to reach $n-2$ segments of crossing depth 0 (which no longer participate in a flip by Lemma 2.6.1 [19, 31]). The last two segments with positive crossing depths are crossing, and flipping them necessarily inserts two segments of crossing depth 0 . The claimed bound follows.

The following theorem provides a quasilinear upper bound in the Convex Tree version.

Theorem 3.2.11 ([17]). Consider a set $S$ of $n$ segments with endpoints $P$ in convex position such that $(P, S)$ forms a tree.

In the Convex Tree version, there exists an untangle sequence of $S$ of length $O(n \log n)$.

In other words, we have the following upper bound:

$$
\mathbf{d}_{\text {Convex Tree }}^{\mathrm{R}}(n)=O(n \log n) .
$$

As we prove the more general Theorem 5.2.1 in the contribution part of this dissertation using some simpler arguments than the proof in [17], we do not provide a proof of Theorem 3.2.11 here.

### 3.2.3 Untangling with Both Choices

In this section, we prove a linear lower bound on $\mathbf{d}_{\text {Convex }}^{\mathrm{RI}}$ Matching and a linear upper bound on $\mathbf{d}_{\text {Convex }}^{\mathrm{RI}}$ Multigraph from the literature.

## Lower Bound

In this section, we prove the following lower bound.
Theorem 3.2.12 ([19]). There exists a set $S$ of $n$ segments with endpoints $P$ in convex position such that $(P, S)$ forms a matching (respectively a bipartite matching, a cycle, a tree), and such that (in the Convex Matching version, respectively in the Convex Bipartite Matching version, in the Convex Cycle version, in the Convex Tree version) any untangle sequence of $S$ is of length at least $n-1=\Omega(n)$ (respectively $n-1=\Omega(n), \frac{n}{2}-1=\Omega(n)$ for even $n, \frac{n-1}{2}=\Omega(n)$ for odd $\left.n\right)$.

In other words, we have the following lower bounds:

$$
\begin{aligned}
\mathbf{d}_{\text {Convex Matching }}^{\mathrm{RI}}(n) & \geq n-1=\Omega(n), \\
\mathbf{d}_{\text {Convex Bipartite Matching }}^{\mathrm{R}}(n) & \geq n-1=\Omega(n), \\
\mathbf{d}_{\text {Convex Cycle }}^{\mathrm{R}}(n) & \geq \frac{n}{2}-1=\Omega(n) \text { for even } n, \\
\mathbf{d}_{\text {Convex Tree }}^{\mathrm{R}}(n) & \geq \frac{n-1}{2}=\Omega(n) \text { for odd } n .
\end{aligned}
$$

In the following, first we define a class of sets of segments called combs, then we prove Theorem 3.2.12 by proving that any untangle sequence of an $n$-comb is of length exactly $n-1$ using splitting to invoke induction.

Combs. We say that a set $S$ of $n$ segments with endpoints $P$ in convex position such that $(P, S)$ forms a bipartite matching is an $n$-comb if there exists a segment $s \in S$ such that $s$ crosses all the segments in $S \backslash\{s\}$ and such that $S \backslash\{s\}$ is crossing free.

Proof of Theorem 3.2.12. Let $S$ be an $n$-comb. We prove by induction on $n$ that the length $f(n)$ of any untangle sequence of $S$ is exactly $n-1$.

If $n=1$, then $S$ contains only $s$ and the claim $f(1)=0$ is trivial.
If $n \geq 2$, then any flip removes $s$ and some other segment $s^{\prime} \in S \backslash\{s\}$. Independently of which pair of segments is inserted, the line $\ell$ containing $s^{\prime}$ does not cross any segment of $S$ after the flip. Thus, $\ell$ splits $S$ into an $n_{1}$-comb $S_{1}$ and an $n_{2}$-comb $S_{2}$, for some $n_{1} \geq 1$ and $n_{2} \geq 1$ such that $n_{1}+n_{2}=n$. This yields the following recurrence relation

$$
f(n)=1+f\left(n_{1}\right)+f\left(n_{2}\right),
$$

which easily solves using induction hypothesis to

$$
f(n)=n-1,
$$

concluding the induction.
This exact same upper bound holds on to $\mathbf{d}_{\text {Convex Bipartite Matching }}^{\mathrm{R}}(n)$ by the transfer reduction (Lemma 2.3.3). It is easy to transform an $n$-comb into a cycle by adding $n$ segments on the convex hull boundary of $P$. These new segments are uncrossable (Lemma 2.6.1) thus do not interfere. The insertion choice is now set to preserve the Cycle property, but the induction above makes no assumption about insertion choice. Therefore, the proof holds in the Convex Cycle version too. Similarly, it easy to remove one of these extra segments to get a path (which is a tree), and to extend the same proof to the Convex Tree version.

## Upper Bound

In this section, we prove the following upper bound. It is originally proven in [17] for the Convex Matching version.

Theorem 3.2.13 ([17]). Consider a multiset $S$ of $n$ segments with endpoints $P$ in convex position.

In the Convex Multigraph version, there exists an untangle sequence of $S$ of length at most $n-1=O(n)$.

In other words, we have the following upper bound:

$$
\mathrm{d}_{\text {Convex Multigraph }}^{\mathrm{RI}}(n) \leq n-1=O(n) .
$$

In the following, we prove Theorem 3.2.13 using removal and insertion choices to iteratively remove a segment of minimal positive crossing depth (defined before Theorem 3.2.7) and insert a segment of null collapsed crossing depth using one flip.

Proof of Theorem 3.2.13. Consider a multiset $S$ of $n$ segments with endpoints $P$ in convex position. Let $p_{1}, \ldots, p_{|P|}$ be the points of $P$ sorted in counterclockwise order along the convex hull boundary.

We repeat the following procedure until there are no more crossings. Let $p_{a} p_{b} \in S$ $(a<b)$ be a segment with crossings (hence, of crossing depth at least one) minimizing
$\delta_{\times}\left(p_{a} p_{b}\right)$. Let $q_{1}, \ldots, q_{\delta \times\left(p_{a} p_{b}\right)}$ be the points defining $\delta_{\times}\left(p_{a} p_{b}\right)$ sorted in counterclockwise order along the convex hull boundary.

Since $p_{a} p_{b}$ has minimum positive crossing depth, the point $q_{1}$ is the endpoint of a segment $q_{1} p_{c} \in S$ that crosses $p_{a} p_{b}$. We chose to remove the segments $q_{1} p_{c}$ and $p_{a} p_{b}$, and to insert the segments $q_{1} p_{a}$ and $p_{b} p_{c}$.

By definition of $q_{1}$, the crossing depth of the inserted segment $q_{1} p_{a}$ is 0 . We have thereby removed two segments with positive crossing depths and inserted at least one segment with null crossing depth. Thus, the number of segments with positive crossing depth decreases by at least 1 at each flip.

Using at most $n-2$ flips is enough to reach $n-2$ segments of crossing depth 0 (which no longer participate in a flip by Lemma 2.6.1 [19, 31]). The last two segments with positive crossing depths are crossing, and flipping them necessarily inserts two segments of crossing depth 0 . The claimed bound follows.

### 3.3 Red-on-a-Line Point Sets

In this section, we present bounds on the length of untangle sequences in the Redonaline Matching version, i.e., in the Bipartite Matching version in the special case where the bipartite point set has all the points of one of its partitions, say the red points, on a common line defining the $x$-axis.

The $x$-axis splits any bipartite matching on such a point set. The splitting lemma (Lemma 2.6.1 [19, 31]) allows to study flips above the $x$-axis and flips below separately. We thus assume that all the blue points lie above the $x$-axis. We call such a point set a red-on-a-line point set.

This special type of point set may be viewed as a transition between the well understood convex bipartite point sets where the red points are on one line $\ell_{1}$ and the blue points are on an other line $\ell_{2}$ parallel to $\ell_{1}$ (this case is fully encoded by permutations and inversions; see Theorem 3.2.1) and the general bipartite point sets.

However, only the upper bound on the length of untangle sequences with removal choice is specific to general red-on-a-line point sets.

### 3.3.1 Untangling with Removal Choice

In this section, we prove a quadratic upper bound on $\mathbf{d}_{\text {Redonaline Matching }}^{R}$ from the literature.

## Upper Bound

In this section, we prove the following upper bound.
Theorem 3.3.1 ([17]). Consider a set $S$ of $n$ segments with endpoints $P$ partitioned into $n$ red points and $n$ blue points such that the red points lie on the $x$-axis, such that the blue points lie above the $x$-axis, and such that $(P, S)$ forms a bipartite matching.

In the Redonaline Matching version, there exists an untangle sequence of $S$ of length at most $n(n-1)=O\left(n^{2}\right)$.

In other words, we have the following upper bound:

$$
\mathbf{d}_{\text {Redonaline Matching }}^{\mathrm{R}}(n) \leq n(n-1)=O\left(n^{2}\right)
$$

The proof of Theorem 3.3.1 invoke the following lemma as a subroutine.

Figure 3.5: Illustration of the proofs (a) of Lemma 3.3.2, (b) of Theorem 3.3.1. This figure appears in [19].

Lemma 3.3.2 ([17]). Consider a set $S$ of $n$ segments with endpoints $P$ partitioned into $n$ red points and $n$ blue points such that the red points lie on the $x$-axis, such that all the blue points lie above the $x$-axis, and such that $(P, S)$ forms a bipartite matching.

If the highest blue point $b$ is matched to the rightmost red point $r$ in $S$, and if all the crossings of $S$ are on the segment rb, then (in the Redonaline Matching version) there exists an untangle sequence of $S$ of length at most $n-1=O(n)$.
Proof. We prove Lemma 3.3.2 by induction on $n$ (Figure 3.5(a) illustrates the proof). If $n=1$, then Lemma 3.3.2 holds.

If $n>1$, then we show that one flip is enough to define a line partitioning the segments in $S$ into two subsets $S_{1}$ and $S_{2}$ such that $S_{2}$ is not empty and has no crossing.

Let $b^{\prime}$ be the first blue point in counterclockwise order around the point $r$ (the ray from $r$ including in the $x$-axis going right is the origin of the angles). Let $r^{\prime}$ be the red point matched to $b^{\prime}$ in $S$. We perform the flip removing the segments $r b, r^{\prime} b^{\prime}$ and inserting $r b^{\prime}, r^{\prime} b$.

After this flip (modifying $S$ in place), the line $r^{\prime} b^{\prime}$ does not cross any segment of $S$ therefore partitioning the segments into two subsets. Let $S_{1}$ be the segments of $S$ lying on the left of the line $r^{\prime} b^{\prime}$ and let $S_{2}$ be the segments of $S$ lying on the right of the line $r^{\prime} b^{\prime}$. The set of segments $S_{2}$ is not empty since it contains at least the segment $r^{\prime} b$. By construction of the point $b^{\prime}$, the segment $r^{\prime} b$ is crossing free. Thus, the segments in $S_{2}$ are all crossing free.

By induction hypothesis, we untangle $S_{1}$ using $n-2$ flips, concluding the proof of Lemma 3.3.2.

Note that the bound of Lemma 3.3.2 is tight. Indeed, there exists a red-on-a-line matching with $n$ segments such that any removal strategy leads to the same untangle sequence of length $n-1$. In fact, any removal strategy is futile as there is exactly one crossing pair of segments before each flip of the only possible untangle sequence (see Figure 3.6 [19]). An alternative proof of this tightness (also holding for convex position) is given by Theorem 3.2.12.

We are now ready to prove Theorem 3.3.1.
Proof of Theorem 3.3.1. We describe an iterative algorithm to untangle $S$ (Figure 3.5(b) illustrates the proof). We label the red points from left to right as follows: $r_{1}, \ldots, r_{n}$.

For $i$ from 1 to $n$, we perform Phase 1 then Phase 2 described next.

Figure 3.6: A lower-bounding untangle sequence of a red-on-a-line matching where only one pair of segments is crossing at each step, thus imposing removal choice. This figure appears in [19].

Loop invariant. Entering the $i$-th loop, all the segments incident to the red points on the left of $r_{i}$ are crossing free.

Phase 1: find a blue point $b$ and insert the segment $r_{i} b$ (using at most $n-i$ flips) such that $b$ is the highest blue point, $r$ is the leftmost red point of a subset $S^{\prime}$ of $S$. We define $b$ as the blue point we reach at the end of the following path $u$. We start the path at $r_{i}$ and we follow the segment incident to $r_{i}$ until we encounter a segment of $S$. We turn left and continue the path on this new segment. We repeat, systematically turning left at every crossing point until we reach a blue point, which we name $b$.

Let $s$ and $s^{\prime}$ be the last two segments we visited in the path $u$. Repeatedly flipping $s, s^{\prime}$ insert the segment $r_{i} b$ after at most $n-i$ flips.

We now define $S^{\prime}$. Let $r_{0}$ and $b_{0}$ be dummy red and blue points such that $r_{0}$ lies on the $x$-axis on the left of all the other red points, such that $b_{0}$ becomes the highest blue point, and such that the segment $r_{0} b_{0}$ is crossing-free. We shoot a horizontal ray from $b$ heading leftwards. Let $r_{j}$ be the red endpoint of the first segment of $S \cup\left\{r_{0} b_{0}\right\}$ hit by this ray, and let $q$ be the hitting point. We finally define $S^{\prime \prime}$ the segments of $S$ which are in the interior of the polygon $q r_{j} r_{i} u b$.

Phase 2: invoke Lemma 3.3.2 on $S^{\prime}$ (using at most $i-1$ flips). The polygon $q r_{j} r_{i} u b$ is convex and is not intersected by any segment of $S$. Therefore, after having applied Lemma 3.3.2, the segments of $S^{\prime}$ are not only not crossing each other but also not crossing other segments of $S \backslash S^{\prime}$. This ensures that the loop invariant holds.

To conclude the proof of Theorem 3.3.1, an upper bound to the total number of flips used by the algorithm is given by the following sum.

$$
\sum_{i=1}^{n}(n-i)+(i-1)=n(n-1)
$$

## Chapter 4

## Untangling with No Choice

In this chapter, we study $\mathbf{d}^{\emptyset}$, the length of the longest untangle sequences in several versions. First, we prove reductions between several versions of $\mathbf{d}^{\emptyset}$. Then, we prove a lower bound, an upper bound parameterized by $t$ (the sum of the degrees of the points which are not in convex position with the rest), and an upper bound in the Redonaline version. Finally, we prove a sub-cubic upper bound on the number of distinct flips in an untangle sequence. This number is not the length of an untangle sequence where the same flip may appear several times (up to a linear number of times) and is counted with its multiplicity.

### 4.1 Reductions

In this section, we provide a series of inequalities relating the different versions of $\mathbf{d}^{\emptyset}$. In particular, we show that all the different versions of $\mathbf{d}^{\natural}$ have the same asymptotic behavior.

Theorem 4.1.1 ([30]). For all positive integer $n$ and for $\Pi$ being either the empty property or the Convex property, we have the following relations:

$$
\begin{align*}
\mathbf{d}_{\Pi \text { Matching }}^{\emptyset}(n) & =\mathbf{d}_{\Pi \text { Multigraph }}^{\emptyset}(n),  \tag{4.1}\\
2 \mathbf{d}_{\Pi \text { Matching }}^{\emptyset}(n) & \leq \mathbf{d}_{\Pi \text { Bipartite Matching }}^{\emptyset}(2 n) \leq \mathbf{d}_{\Pi \text { Matching }}^{\emptyset}(2 n),  \tag{4.2}\\
2 \mathbf{d}_{\Pi \text { Bipartite Matching }}^{\emptyset}(n) & \leq \mathbf{d}_{\Pi \text { Cycle }}^{\emptyset}(3 n) \leq \mathbf{d}_{\Pi \text { Matching }}^{\emptyset}(3 n),  \tag{4.3}\\
2 \mathbf{d}_{\Pi \text { Bipartite Matching }}^{\emptyset}(n) & \leq \mathbf{d}_{\Pi \text { Tree }}^{\emptyset}(3 n) \leq \mathbf{d}_{\Pi \text { Matching }}^{\emptyset}(3 n) . \tag{4.4}
\end{align*}
$$

Proof. Equality (4.1) can be rewritten $\mathbf{d}_{\Pi}^{\emptyset}$ Multigraph $(n) \leq \mathbf{d}_{\Pi}^{\emptyset}$ Matching $(n) \leq \mathbf{d}_{\Pi}^{\emptyset}$ Multigraph $(n)$. Hence, we have to prove eight inequalities. The right-side inequalities follow from Lemma 2.3.2, since the left-side property is stronger than the right-side property (using the equality (4.1) for inequalities (4.3) and (4.4)).

The proofs of the remaining inequalities follow the same structure: given a flip sequence of the left-side version, we build a flip sequence of the right-side version, having similar length and number of points.

We first prove all the inequalities assuming that $\Pi$ is the empty property. Preserving the Convex property follows from the fact that the extra copy a point added by the following reductions is placed in convex position while still being close enough to its original location (Figure 4.1(a)).

Proving $\mathbf{d}_{\Pi \text { Multigraph }}^{\emptyset}(n) \leq \mathbf{d}_{\Pi \text { Matching }}^{\natural}(n)$ (4.1). We prove the left inequality of (4.1). A point of degree $d^{\circ}$ larger than 1 can be replicated as $d^{\circ}$ points that are arbitrarily close to each other in order to produce a matching of $2 n$ points. This replication preserves the crossing pairs of segments, possibly creating new crossings (Figure 4.1(a)). Thus, for any flip sequence in the Multigraph version, there exists a flip sequence in the Matching version of equal length, yielding $\mathbf{d}_{\Pi}^{\emptyset}$ Multigraph $(n) \leq \mathbf{d}_{\Pi}^{\emptyset}$ Matching $(n)$.

Figure 4.1: (a) A crossing-free multigraph transformed into a matching by replacing multi-degree points by clusters of points. This transformation (like the next ones) preserves the property that a set of points is in convex position (their convex hull boundary is dashed-dotted). (b) Two flips in the Bipartite Matching version simulating one flip in the Matching version. (c) Two flips in the Cycle version simulating one flip in the Bipartite Matching version. (d) Two flips in the Tree version simulating one flip in the Bipartite Matching version.

Proving $2 \mathbf{d}_{\Pi}^{\natural}{ }_{\text {Matching }}(n) \leq \mathbf{d}_{\Pi}^{\emptyset}$ Bipartite Matching $(2 n)$ (4.2). The left inequality of (4.2) is obtained by duplicating the monochromatic points of the matching $S$ into two arbitrarily close points, one red and the other blue. Then each segment of $S$ is also duplicated into two red-blue segments. We obtain a bipartite matching $S^{\prime}$ with $2 n$ segments. A crossing in $S$ corresponds to four crossings in $S^{\prime}$. Flipping this crossing in $S$ amounts to choose which of the two possible pairs of segments replaces the crossing pair. It is simulated by flipping the two crossings in $S^{\prime}$ such that the resulting pair of double segments corresponds to the resulting pair of segments of the initial flip. These two crossings always exist and it is always possible to flip them one after the other as they involve disjoint pairs of segments. Figure 4.1(b) shows this construction. A sequence of $k$ flips on $S$ provides a sequence of $2 k$ flips on $S^{\prime}$. Hence, $2 \mathbf{d}_{\Pi}^{\emptyset}$ Matching $(n) \leq \mathbf{d}_{\Pi}^{\emptyset}$ Bipartite Matching $(2 n)$.

Proving $2 \mathbf{d}_{\Pi}^{\emptyset}$ Bipartite Matching $(n) \leq \mathbf{d}_{\Pi}^{\emptyset}{ }_{\text {Cycle }}(3 n)$ (4.3). To prove the left inequality of (4.3), we start from a bipartite matching $S$ with $2 n$ points and $n$ segments and build a cycle $S^{\prime}$ with $3 n$ points and $3 n$ segments. We then show that the flip sequence of length $k$ on $S$ provides a flip sequence of length $2 k$ on $S^{\prime}$. We build $S^{\prime}$ in the following way. Given a red-blue segment $r b \in S$, the red point $r$ is duplicated in two arbitrarily close points $r$ and $r^{\prime}$ which are adjacent to $b$ in $S^{\prime}$. We still need to connect the points $r$ and $r^{\prime}$ in order to obtain a cycle $S^{\prime}$. We define $S^{\prime}$ as the cycle $r_{1}, b_{1}, r_{1}^{\prime}, \ldots, r_{i}, b_{i}, r_{i}^{\prime}, \ldots, r_{n}, b_{n}, r_{n}^{\prime} \ldots$ where $r_{i}$ is matched to $b_{i}$ in $S$ (Figure 4.1(c)).

We now show that a flip sequence of $S$ with length $k$ provides a flip sequence of $S^{\prime}$ with length $2 k$. For a flip on $S$ removing the pair of segments $r_{i} b_{i}, r_{j} b_{j}$ and inserting the pair of segments $r_{i} b_{j}, r_{j} b_{i}$, we perform the following two successive flips on $S^{\prime \prime}$.

- The first flip removes $r_{i} b_{i}, r_{j}^{\prime} b_{j}$ and inserts $r_{i} b_{j}, r_{j}^{\prime} b_{i}$.
- The second flip removes $r_{i}^{\prime} b_{i}, r_{j} b_{j}$ and inserts $r_{i}^{\prime} b_{j}, r_{j} b_{i}$.

The cycle then becomes $r_{1}, b_{1}, r_{1}^{\prime}, \ldots, r_{i}, b_{j}, r_{i}^{\prime}, \ldots, r_{j}, b_{i}, r_{j}^{\prime}, \ldots, r_{n}, b_{n}, r_{n}^{\prime}, \ldots$ on which we can apply the next flips in the same way. Hence, $2 \mathbf{d}_{\Pi}^{\emptyset}$ Matching $(n) \leq \mathbf{d}_{\Pi}^{\emptyset}$ Cycle $(3 n)$.

Proving $2 \mathbf{d}_{\Pi \text { Bipartite }}^{\natural}$ Matching $^{\emptyset}(n) \leq \mathbf{d}_{\Pi \text { Tree }}^{\emptyset}(3 n)$ (4.4). The proof of the left inequality of (4.4) follows the exact same construction as in the proof of the left inequality of (4.3). The only difference is that, in order for $S^{\prime}$ to form a tree and not a cycle, we omit the segment $r_{n}^{\prime} r_{1}$, yielding a polygonal line which is a tree (Figure 4.1(d)).

### 4.2 Lower Bound for Red-on-a-Line Matchings

In this section, we prove the following quadratic lower bound. Although this lower bound only improves the state of the art by a constant factor, its proof nonetheless exhibits the longest untangle sequence ever know. This untangle sequence is 1.5 times longer than the longest untangle sequence in the Convex Bipartite Multigraph version. To achieve this 1.5 factor, we take advantage of the non-convex aspect in a non-intuitive fashion.

Theorem 4.2.1 ([33]). In the Redonaline Matching version for even n, there exists a set $S$ of $n$ segments with endpoints $P$ partitioned into $n$ red points and $n$ blue points such that the red points lie on the $x$-axis, such that the blue points lie above the $x$-axis, such that $(P, S)$ forms a bipartite matching, and such that there exists an untangle sequence of $S$ of length $\frac{3}{2}\binom{n}{2}-\frac{n}{4}=\Omega\left(n^{2}\right)$.

In other words, for even $n$, we have the following lower bound:

$$
\mathbf{d}_{\text {Redonaline Matching }}^{\emptyset}(n) \geq \frac{3}{2}\binom{n}{2}-\frac{n}{4}=\Omega\left(n^{2}\right)
$$

To prove Theorem 4.2.1, it suffices to present a long untangle sequence. The initial matching of the sequence is represented in Figure 4.2.

Figure 4.2: A 3-butterfly to lower bound $\mathbf{d}^{\emptyset}(6)$.
We provide a $2 m$-segment red-on-a-line matching which we call an $m$-butterfly. There exists an untangle sequence starting at an $m$-butterfly of length $\frac{3}{2}\binom{2 m}{2}-\frac{m}{2}$. Next, we give the precise definition of an $m$-butterfly and some of its important properties. Then, we give some intuition of how to come up with an untangle sequence longer than the number of pairs of segments. Finally, we prove that there exists an untangle sequence starting at an $m$-butterfly of length $\frac{3}{2}\binom{2 m}{2}-\frac{m}{2}$ with two lemmas.

Butterfly. For an integer $m$, we define an $m$-butterfly as the following matching with $n=2 m$ segments. For $i$ from 1 to $m$ we have red points $r_{i}=(i /(m+1), 0)$ and $r_{i}^{\prime}=(-i /(m+1), 0)$ as well as blue points $b_{i}=(i-(m+1),(m+1)-i)$ and $b_{i}^{\prime}=((m+1)-i,(m+1)-i)$. We match $r_{i}$ to $b_{i}$ and $r_{i}^{\prime}$ to $b_{i}^{\prime}$. Next, we discuss important properties of an $m$-butterfly.

We call a red-on-a-line convex matching an $n$-star if all the $\binom{n}{2}$ pairs of segments cross. We say that an $n$-star looks at a point $p$ if the blue points are all on a common line, and if $p$ is the intersection of this line with the line of the red points. We also say that two red-blue point sets $R, B$ and $R^{\prime}, B^{\prime}$ are fully crossing if all the pairs of segments of the form $\left\{r b, r^{\prime} b^{\prime}\right\}$ cross, where $\left(r, b, r^{\prime}, b^{\prime}\right) \in R \times B \times R^{\prime} \times B^{\prime}$. Two matchings are fully crossing if their underlying red-blue point sets are fully crossing. An $m$-butterfly is a red-on-a-line matching consisting of two fully crossing $m$-stars both looking at the same point $o=(0,0)$ (Figure 4.2 represents these properties but it is not drawn to scale).

Intuition. In the following, we use the state tracking framework from Section 5.8 to describe how to come up with an untangle sequence starting at an $m$-butterfly with more than $\binom{2 m}{2}$ flips. We consider a sequence of tracking choices with no $\mathbf{H} \rightarrow \mathbf{X}$ transition (Lemma 5.8.2) for the long untangle sequence we build. We take advantage of the non-convex position of the blue points to create flip situations such as in Figure 5.12(a), where an $\mathbf{H}$-pair is turned into a T-pair.

For instance, let us consider an $\mathbf{X}$-pair of one of the $m$-stars composing the $m$ butterfly. At some point of the untangle sequence, we flip this X-pair, turning it into an H-pair. Later on, we turn this H-pair into a T-pair, as in Figure 5.12(a). Still later on, we turn this T-pair into an X-pair again, similarly to the pairs involving the smallest horizontal segment in Figure 1.2. This $\mathbf{X}$-pair will be flipped again.

We manage to carry out this whole process to flip twice all the $2\binom{m}{2}$ pairs of the two $m$-stars composing the $m$-butterfly while still having one flip for every other pair. In total, we reach $\frac{3}{2}\binom{2 m}{2}-\frac{m}{2}$ flips.
Proof of Theorem 4.2.1. We exhibit an untangle sequence starting at any $m$-butterfly of length $\frac{3}{2}\binom{2 m}{2}-\frac{m}{2}$ (Figure 4.3 and Figure 4.4). The untangle sequence can be divided into two phases.

The first phase consists of (i) $\binom{m}{2}$ flips applied to the $m$-star submatching defined by the $m$ leftmost red points (see the proof of Theorem 3.2.1 [19], and Figure 4.3, steps 0 to 3), and of (ii) $\binom{m}{2}$ more flips applied to the $m$ rightmost red points (Figure 4.3, steps 3 to 6 ). At this point, we have two sets of $m$ crossing-free segments, each set fully crossing the other.

The second phase repeats $m$ times the following routine.

1. Flip the segments defined by the innermost red points $r_{1}$ and $r_{1}^{\prime}$ (Figure 4.3 and 4.4, steps 6 to 7,11 to 12 , and 16 to 17). After this flip, the submatching defined by the $m$ leftmost red points and their matched points consists of $m-1$ crossing-free segments intersected by the segment from $r_{1}^{\prime}$. A similar statement holds for the submatching defined by the $m$ rightmost red points.
2. Untangle the submatching defined by the $m$ leftmost red points with $m-1$ flips in the following manner (Figure 4.3 and 4.4, steps 7 to 9,12 to 14 , and 17 to
19). Flip of the two crossing segments with the rightmost red points, say $r_{k}^{\prime}$ and $r_{k+1}^{\prime}$ with $k \in\{1, \ldots, m-1\}$, and repeat. Such a flip produces a segment from $r_{k+1}^{\prime}$ crossing the segments whose red points are on the left of $r_{k+1}$, and an other segment from $r_{k}^{\prime}$ crossing none of segments of the submatching. The number of crossings in the submatching decreases by 1 at each flip.
3. Similarly, untangle the $m$ rightmost red points with $m-1$ more flips (Figure 4.3 and 4.4 , steps 9 to 11,14 to 16 , and 19 to 21 ).

Each loop decreases the number of "long" segments (i.e., segments joining one of the leftmost red points to one of the rightmost blue points, or vice-versa) by 2 . At the end of the process, the left submatching is crossing-free; so is the right one; and the two of them do not intersect anymore.

Summing up, the total length of the untangle sequence is $2\binom{m}{2}+2 m(m-1)+m$. Simple calculation yields Theorem 4.2.1.

### 4.3 Upper Bound for Near Convex Position

In this section, we bridge the gap between the $O\left(n^{2}\right)$ bound on the length of untangle sequences for a set $P$ of points in convex position and the $O\left(n^{3}\right)$ bound for $P$ in general position. We prove the following theorem in the Matching version; the translations to the other versions follows from the reductions in Theorem 4.1.1.

Theorem 4.3.1 ([30]). Consider a multiset $S$ of $n$ segments with endpoints $P$ partitioned into $P=C \cup T$ where $C$ is in convex position. We define the parameter $t$ as the sum of the degrees of the points in $T$.

In the Multigraph version, any untangle sequence of $S$ is of length $O\left(t n^{2}\right)$.
In other words, we have the following upper bound:

$$
\mathbf{d}_{\text {Multigraph }}^{\emptyset}(n, t)=O\left(t n^{2}\right) .
$$

Proof. The proof strategy is to combine the potential $\chi$ used in the proof of Theorem 3.2.2 [17] with the potential $\Lambda_{L}$ used in the proof of Theorem 3.1.3 [82]. Given a matching $S$, the potential $\chi(S)$ is defined as the number of crossing pairs of segments in $S$. Since there are $n$ segments in $S, \chi(S) \leq\binom{ n}{2}=O\left(n^{2}\right)$. Unfortunately, with points in non-convex position, a flip $f$ might increase (or leave unchanged) $\chi$, i.e. $\chi(f(S)) \geq \chi(S)$ (as shown in Figure 1.2).

The potential $\Lambda_{L}$ is derived from the line potential introduced in [83] but instead of using the set of all the $O\left(n^{2}\right)$ lines through two points of $P$, we use a subset of $O(t n)$ lines in order to take into account that only $t$ points are in non-convex position. More precisely, let the potential $\Lambda_{\ell}(S)$ of a line $\ell$ be the number of segments of $S$ crossing $\ell$. Note that $\Lambda_{\ell}(S) \leq n$. The potential $\Lambda_{L}(S)$ is then defined as follows: $\Lambda_{L}(S)=\sum_{\ell \in L} \Lambda_{\ell}(S)$.

We now define the set of lines $L$ as the union of $L_{1}$ and $L_{2}$, defined hereafter. Let $C$ be the subset containing the $2 n-t$ points of $P$ which are in convex position. Let $L_{1}$ be the set of the $O(t n)$ lines through two points of $P$, at least one of which is not in $C$.

Figure 4.3: First part of an untangle sequence starting at a 3-butterfly of length 21 illustrating Theorem 4.2.1 and its proof. Each line corresponds to a portion of the proof, with repetitions added for clarity.

Figure 4.4: Second part of an untangle sequence starting at a 3-butterfly of length 21 illustrating Theorem 4.2.1 and its proof. Each line corresponds to a portion of the proof, with repetitions added for clarity.

Let $L_{2}$ be the set of the $O(n)$ lines through two points of $C$ which are consecutive on the convex hull boundary of $C$.

Let the potential $\Phi(S)=\chi(S)+\Lambda_{L}(S)$. We have the following bounds: $0 \leq \Phi(S) \leq$ $O\left(t n^{2}\right)$. To complete the proof of Theorem 4.3.1, we show that any flip decreases $\Phi$ by at least 1 .

We consider an arbitrary flip $f$ removing the pair of segments $p_{1} p_{3}, p_{2} p_{4}$ and inserting the pair of segments $p_{1} p_{4}, p_{2} p_{3}$. Let $o$ be the point of intersection of $p_{1} p_{3}$ and $p_{2} p_{4}$. It is shown in Lemma 3.1.1 [83] that $f$ never increases the potential $\Lambda_{\ell}$ of a line $\ell$. More precisely, we have the following three cases:

- The potential $\Lambda_{\ell}$ decreases by 1 if the line $\ell$ separates the final segments $p_{1} p_{4}$ and $p_{2} p_{3}$ and exactly one of the four flipped points belongs to $\ell$. We call these lines $f$-critical (Figure 4.5(a)).
- The potential $\Lambda_{\ell}$ decreases by 2 if the line $\ell$ strictly separates the final segments $p_{1} p_{4}$ and $p_{2} p_{3}$. We call these lines $f$-dropping (Figure 4.5(b)).
- The potential $\Lambda_{\ell}$ remains stable in the remaining cases.

Notice that, if a point $q$ lies in the triangle $p_{1} o p_{4}$, then the two lines $q p_{1}$ and $q p_{4}$ are $f$-critical (Figure 4.5(a)).

(a)

(b)

Figure 4.5: (a) An $f$-critical line $\ell$ for a flip $f$ removing $p_{1} p_{3}, p_{2} p_{4}$ and inserting $p_{1} p_{4}, p_{2} p_{3}$. This situation corresponds to case (2a) with $\ell \in L_{1}$. (b) An $f$-dropping line $\ell$. This situation corresponds to case (2b) with $\ell \in L_{2}$.

To prove that $\Phi$ decreases, we have the following two cases.
Case 1. If $\chi$ decreases, as the other term $\Lambda_{L}$ does not increase, then their sum $\Phi$ decreases as desired.

Case 2. If not, then $\chi$ increases by an integer $k$ with $0 \leq k \leq n-1$, and we know that there are $k+1$ new crossings after the flip $f$. Each new crossing involves a distinct segment with one endpoint, say $q_{i}(0 \leq i \leq k)$, inside the non-simple polygon $p_{1}, p_{4}, p_{2}, p_{3}$ (Figure 4.5). Next, we show that each point $q \in\left\{q_{0}, \ldots, q_{k}\right\}$ maps to a distinct line in $L$ which is either $f$-dropping or $f$-critical, thus proving that the potential $\Lambda_{L}$ decreases by at least $k+1$.

We assume without loss of generality that $q$ lies in the triangle $p_{1} o p_{4}$. We consider the two following cases.

Case 2a. If at least one among the points $q, p_{1}, p_{4}$ is not in $C$, then either $q p_{1}$ or $q p_{4}$ is an $f$-critical line $\ell \in L_{1}$ (Figure 4.5(a)).

Case 2b. If not, then $q, p_{1}, p_{4}$ are all in $C$, and the two lines through $q$ in $L_{2}$ are both either $f$-dropping (the line $\ell$ in Figure $4.5(\mathrm{~b})$ ) or $f$-critical (the line $q p_{4}$ in

Figure $4.5(\mathrm{~b})$ ). Consequently, there are more lines $\ell \in L_{2}$ that are either $f$-dropping or $f$-critical than there are such points $q \in C$ in the triangle $p_{1} o p_{4}$, and the theorem follows.

### 4.4 Upper Bound for Red-on-a-Line Matchings

In this section we prove the following theorem.
Theorem 4.4.1 ([33]). Consider a set $S$ of $n$ segments with endpoints $P$ partitioned into $n$ red points and $n$ blue points such that the red points lie on the $x$-axis, such that the blue points lie above the $x$-axis, and such that $(P, S)$ forms a bipartite matching.

In the Redonaline Matching version, any untangle sequence of $S$ is of length at most $\binom{n}{2} \frac{n+4}{6}=O\left(n^{3}\right)$.

In other words, we have the following upper bound:

$$
\mathbf{d}_{\text {Redonaline Matching }}^{\emptyset}(n) \leq\binom{ n}{2} \frac{n+4}{6}=O\left(n^{3}\right)
$$

To prove Theorem 4.4.1, we define a potential function $\Phi$ that maps a red-on-a-line matching to an integer from 0 to $\binom{n}{2} \frac{n+4}{3}$. Since $\Phi$ decreases by at least 2 at each flip, the theorem follows. We first give the definitions needed to present $\Phi$. Then, we prove four lemmas yielding Theorem 4.4.1.

Let $S$ be a red-on-a-line matching. Let $r_{1}, \ldots, r_{n}$ be the red points, from left to right. Let $\ell$ be a line, parallel to the line of the red points and above all the points. For each $k$ in $\{1, \ldots, n\}$, we project the blue points onto $\ell$, using $r_{k}$ as a focal point. More precisely, each blue point $b$ maps to a point $t_{k}(b)$, the intersection between the ray $r_{k} b$ and the line $\ell$ (Figure 4.6(a)). We also define the function $t_{k}$ of a red-blue segment $r b$ as the segment $t_{k}(r b)=r t_{k}(b)$ (Figure 4.6(b)).

(a)

(b)

Figure 4.6: (a) The projection $t_{k}$ for $k=3$. (b) The segments $t_{3}(\cdot)$. The four 3 -observed crossing 3-pairs are circled.

We may abbreviate a pair of segments $r_{i} b, r_{j} b^{\prime}$ as $\langle i, j\rangle$ when the points $b$ and $b^{\prime}$ can be deduced from the underlying matching. Let $k$ be an integer in $\{1, \ldots, n\}$. We say that two segments are $k$-observed crossing if the extended projection $t_{k}(\cdot)$ maps them to crossing segments (Figure 4.6(b)). A pair of segments $\langle i, j\rangle$ is a $k$-pair if $i \leq k \leq j$. A $k$-flip is then a flip of a $k$-pair. We have the following lemma.

Lemma 4.4.2. A crossing $k$-pair is necessarily $k$-observed crossing.
Proof. Let $r_{i} b, r_{j} b^{\prime}$ be a crossing $k$-pair. We suppose, without loss of generality, that $i<j$ (e.g. $i=2, k=3$, and $j=5$ in Figure 4.6).

The fact that the $k$-pair $r_{i} b, r_{j} b^{\prime}$ is crossing means that the four points are in convex position, and that they appear as $r_{i}, r_{j}, b, b^{\prime}$ on their convex hull in counter-clockwise order. Since $i \leq k \leq j$, the point $r_{k}$ is also on the boundary of the convex hull of the four points. Therefore, the projection $t_{k}(\cdot)$ will not change the convex-hull order and the segments $r_{i} t_{k}(b)$ and $r_{j} t_{k}\left(b^{\prime}\right)$ will cross.

We define $\Phi_{k}(S)$, the $k$-th potential of $S$, as the number of $k$-observed crossing $k$-pairs (Figure 4.6(b)). Lemma 4.4.3 shows that the $k$-th potential $\Phi_{k}$ is at most $(k-1)(n-k)+n-1$. Lemma 4.4.4 shows that $\Phi_{k}$ never increases, and decreases by at least 1 at each $k$-flip.

Lemma 4.4.3. The $k$-th potential $\Phi_{k}$ takes integer values from 0 to $k(n+1)-k^{2}-1$.
Proof. The $k$-th potential $\Phi_{k}(S)$ is at most the number of $k$-pairs in $S$, crossing or not. There are exactly $(k-1)(n-k) k$-pairs of the form $\langle i, j\rangle$ with $i<k<j$. There are exactly $k-1 k$-pairs of the form $\langle i, k\rangle$ with $i<k$. There are exactly $n-k k$-pairs of the form $\langle k, j\rangle$ with $k<j$. In total, there are $k(n+1)-k^{2}-1 k$-pairs in $S$.

Lemma 4.4.4. The $k$-th potential $\Phi_{k}$ never increases, and decreases by at least 1 at each $k$-flip.

Proof. We order the projected blue points on $\ell$ from left to right. We then map each projected blue point $t_{k}(b)$ to an element in $\{\swarrow, \downarrow, \searrow\}$ :

- $t_{k}(b)$ is mapped to $\swarrow$ if $b$ is matched to a red point on the left of $r_{k}$,
- $t_{k}(b)$ is mapped to $\downarrow$ if $b$ is matched to $r_{k}$,
- $t_{k}(b)$ is mapped to $\searrow$ if $b$ is matched to a red point on the right of $r_{k}$.

Let $w=w_{1} \ldots w_{n}$ be the word on the alphabet $\{\swarrow, \downarrow, \searrow\}$ induced by the order of the projected blue points and the map. For instance, in Figure 4.6 with $k=3$, $w=\searrow \swarrow \swarrow \searrow \downarrow \searrow$.

Let the total order of the symbols be $\swarrow \prec \downarrow \prec \searrow$. An inversion in $w$ is a pair $w_{i}, w_{j}$ with $i<j$ and $w_{j} \prec w_{i}$. The inversions in $w$ are in bijection with the $k$-observed crossing $k$-pairs in $S$. Thus, by definition, $\Phi_{k}(S)$ is the number of inversions in $w$. Lemma 4.4.4 follows from the following two observations.
(i) Any flip which is not a $k$-flip swaps two $\swarrow$ or two $\searrow$ in $w$, resulting in word $w^{\prime}$ identical to $w$.
(ii) Lemma 4.4.2 ensures that a crossing $k$-pair corresponds to an inversion in $w$. Thus, a $k$-flip exchanges the two symbols of an inversion in $w$, resulting in word $w^{\prime}$ with at least one inversion less than in $w$.

We now define $\Phi(S)$, the potential of $S$, as the sum of $\Phi_{k}(S)$, for $k$ in $\{1, \ldots, n\}$. The following lemma presents the key properties of $\Phi$.

Lemma 4.4.5. The potential $\Phi$ takes integer values from 0 to $\binom{n}{2} \frac{n+4}{3}$, and decreases by at least 2 at each flip.

Proof. We know that $\Phi$ takes non-negative integer values by definition. By Lemma 4.4.3, an upper bound on $\Phi$ is

$$
\begin{aligned}
\sum_{k=1}^{n}\left(k(n+1)-k^{2}-1\right) & =(n+1) \sum_{k=1}^{n} k-\sum_{k=1}^{n} k^{2}-n \\
& =(n+1) \frac{n(n+1)}{2}-\frac{n(n+1)(2 n+1)}{6}-n \\
& =\frac{n}{6}\left(n^{2}+3 n-4\right) \\
& =\binom{n}{2} \frac{n+4}{3} .
\end{aligned}
$$

Finally, Lemma 4.4.4 ensures that $\Phi$ decreases by at least 2 at each flip. Indeed, a flip of a pair $\langle i, j\rangle$ is counted at least twice: once in $\Phi_{i}$ as an $i$-flip, and once in $\Phi_{j}$ as a $j$-flip.

Theorem 4.4.1 follows from Lemma 4.4.5.

### 4.5 Upper Bound without Multiplicity

In this section, we prove the following theorem in the Matching version, yet, the proof can easily be adapted to the other versions. We recall that two flips are distinct if the set of the two removed and the two inserted segments of one flip is distinct from the set with the same definition of the other flip. Note that there exist flip sequences (even in the Permutation version) using the same flip a linear number of time (Figure 4.7 [19]). However, it is unknown whether removal choice may be used to avoid using the same flip, or whether there exist multisets of segments such that any untangle sequence reuse at least a flip.

Figure 4.7: A flip sequence in the Permutation version where the highlighted segments $r_{2} b_{3}, r_{3} b_{2}$ are removed than reinserted and flipped again. It is possible to iterate the use of this same flip up to $\frac{n}{2}$ for even $n$. The first three flips of this figure appear in [19].

Theorem 4.5.1 ([30]). Consider a multiset $S$ of $n$ segments with endpoints $P$.
In the Multigraph version, any untangle sequence of $S$ has $O\left(n^{8 / 3}\right)$ distinct fips.

The proof of Theorem 4.5.1 is based on a balancing argument from [44] and is decomposed into two lemmas that consider a flip $f$ and two matchings $S$ and $S^{\prime}=f(S)$. Similarly to the proof of Theorem 3.1.3 [83], let $L$ be the set of lines defined by all pairs of points in $\binom{P}{2}$. For a line $\ell \in L$, let $\Lambda_{\ell}(S)$ be the number of segments of $S$ crossed by $\ell$ and $\Lambda_{L}(S)=\sum_{\ell \in L} \Lambda_{\ell}(S)$. Notice that $\Lambda_{L}(S)-\Lambda_{L}\left(S^{\prime}\right)$ depends only on the flip $f$ and not on $S$ or $S^{\prime}$. The following lemma follows immediately from the fact that $\Lambda_{L}(S)$ takes integer values between 0 and $O\left(n^{3}\right)$.

Lemma 4.5.2. For any integer $k$, the number of flips $f$ in a flip sequence with $\Lambda_{L}(S)-\Lambda_{L}\left(S^{\prime}\right) \geq k$ is $O\left(n^{3} / k\right)$.

Lemma 4.5.2 bounds the number of flips (distinct or not) that produce a large potential drop in a flip sequence. Next, we bound the number of distinct flips that produce a small potential drop. The bound considers all possible flips on a fixed set of points and does not depend on a particular flip sequence.

Lemma 4.5.3. For any integer $k$, the number of distinct fips $f$ with $\Lambda_{L}(S)-\Lambda_{L}\left(S^{\prime}\right)<k$ is $O\left(n^{2} k^{2}\right)$.

Proof. Let $F$ be the set of flips with $\Lambda_{L}(S)-\Lambda_{L}\left(S^{\prime}\right)<k$ where $S^{\prime}=f(S)$. We need to show that $|F|=O\left(n^{2} k^{2}\right)$. Consider a flip $f \in F$ removing the pair of segments $p_{1} p_{3}, p_{2} p_{4}$ and inserting the pair of segments $p_{1} p_{4}, p_{2} p_{3}$. Next, we show that there are at most $4 k^{2}$ such flips with a fixed final segment $p_{1} p_{4}$. Since there are $O\left(n^{2}\right)$ possible values for $p_{1} p_{4}$, the lemma follows. We show only that there are at most $2 k$ possible values for $p_{3}$. The proof that there are at most $2 k$ possible values for $p_{2}$ is analogous.

Figure 4.8: Illustration for the proof of Lemma 4.5.3.
We sweep the points in $P \backslash\left\{p_{4}\right\}$ by angle from the ray $p_{1} p_{4}$. As shown in Figure 4.8, let $q_{1}, \ldots, q_{k}$ be the first $k$ points produced by this sweep in one direction, $q_{-1} \ldots, q_{-k}$ in the other direction and $Q=\left\{q_{-k} \ldots, q_{-1}, q_{1}, \ldots, q_{k}\right\}$. To conclude the proof, we show that $p_{3}$ must be in $Q$. Suppose $p_{3} \notin Q$ for the sake of a contradiction and assume without loss of generality that $p_{3}$ is on the side of $q_{i}$ with positive $i$. Then, consider the lines $L^{\prime}=\left\{p_{1} q_{1}, \ldots, p_{1} q_{k}\right\}$. Notice that $L^{\prime} \subseteq L,\left|L^{\prime}\right|=k$, and for each $\ell \in L^{\prime}$ we have $\Lambda_{\ell}(S)>\Lambda_{\ell}\left(S^{\prime}\right)$, which contradicts the hypothesis that $\Lambda_{L}(S)-\Lambda_{L}\left(S^{\prime}\right)<k$.

Theorem 4.5.1 is a consequence of Lemmas 4.5.2 and 4.5.3 with $k=n^{1 / 3}$. S

## Chapter 5

## Untangling with Removal Choice

In this chapter, we first exhibit a bipartite matching on a point set in convex position such that every of its untangle sequences is long, therefore improving the lower bound on $\mathrm{d}_{\text {Convex }}^{\mathrm{R}}$ by a constant factor.

Then, we devise strategies for removal choice to untangle multisets of segments with endpoints $P=C \cup T$ (where $C$ is in convex position), therefore providing upper bounds for several point set versions of $\mathbf{d}_{\text {Multigraph }}^{\mathrm{R}}$. Recall that such insertion strategies choose which pair of crossing segments is removed, but not which pair of segments with the same endpoints is subsequently inserted. We start with a point set in convex position (the Convex version), followed by 1 point inside or outside the convex (the $|\mathrm{T}|=1$ version), then 1 point inside and 1 outside the convex (the Inout version), 2 points inside the convex (the Inin version), and 2 points outside the convex (the Outout version). The last three proofs are somewhat similar but the proof of the Inout version is quite less tedious. As only removal choice is used, all results also apply to all the flip versions.

### 5.1 Lower Bound for Convex Bipartite Matchings

In this section, we prove the following linear lower bound on $\mathbf{d}_{\text {Convex }}^{\mathrm{R}}$ Bipartite Matching.
Theorem 5.1.1 ([33]). Let $n$ be an even non-negative integer. There exist a set $S$ of $n$ segments with endpoints $P$ in convex position partitioned into $n$ red points and $n$ blue points, such that $(P, S)$ forms a bipartite matching, and such that (in the Convex Bipartite Matching version) any untangle sequence of $S$ is of length $\frac{3}{2} n-2$.

In particular, we have the following lower bound (for even $n$ ):

$$
\mathbf{d}_{\text {Convex Bipartite Matching }}^{\mathrm{R}}(n) \geq \frac{3}{2} n-2=\Omega(n) .
$$

To prove Theorem 5.1.1, we need to show that every untangle sequence starting at a given configuration (represented in Figure 5.1) is long enough. We do so by showing that every flip reduces the number of crossings by exactly 1 .

We provide a convex bipartite matching which we call an $m$-fence, with $2 m$ segments and $3 m-2$ crossings (Figure 5.1). Next, we give the precise definition of an $m$-fence, together with some useful terminology. Then, we prove Theorem 5.1.1 with three

Figure 5.1: A 5 -fence to lower bound $\mathbf{d}^{\mathrm{R}}(10)$.
lemmas inferring that all untangle sequences starting at an $m$-fence have length $3 m-2$, that is, each flip reduces the number of crossings by exactly 1 .

Fence. Let $q_{2 m+2}, q_{2 m}, q_{2 m-1}, \ldots, q_{4}, q_{3}, q_{1}, p_{1}, p_{3}, p_{4}, \ldots, p_{2 m-1}, p_{2 m}, p_{2 m+2}$ be $4 m$ points in convex position, ordered counter-clockwise, and with colors alternating every two points (Figure 5.1). More precisely, points $p_{i}, q_{i}$ are red if $i \equiv 1,2 \bmod 4$ and blue otherwise. We deliberately avoid using the indices 2 and $2 m+1$ to simplify the description. The segments of an $m$-fence are the $p_{i} q_{i+3}$ and the $q_{i} p_{i+3}$ where $i$ is odd and varies between 1 and $2 m-1$.

For $1 \leq k \leq m+1$, the $k$-th column consists of the at most 4 points with indices $2 k-1$ and $2 k$. We say that a convex bipartite matching with the same point set as an $m$-fence is a derived $m$-fence if, for all $k \in\{2, \ldots, m\}$, for all $w \in\{p, q\}$, one of the following statements holds:

1. $w_{2 k-1}$ is matched to a point of the $(k-1)$-th column, and $w_{2 k}$ is matched to a point of the $(k+1)$-th column, or
2. $w_{2 k-1}$ is matched to a point of the $(k+1)$-th column, and $w_{2 k}$ is matched to a point of the $(k-1)$-th column.

Five examples of derived $m$-fences are presented in Figure 5.2. Note that an $m$-fence is in particular a derived $m$-fence.

When statement 2 holds, the two segments cross. We call such a crossing an end crossing. Similarly, a middle crossing is a crossing of the form $\left\{p_{i} q_{j}, q_{i^{\prime}} p_{j^{\prime}}\right\}$, where $i$ and $i^{\prime}$ are of the same column, and $j$ and $j^{\prime}$ are of the same column.

Proof of Theorem 5.1.1. To prove Theorem 5.1.1, we first show with two lemmas that a flip changes a derived $m$-fence into another derived $m$-fence. Finally, we show that a flip of a derived $m$-fence reduces its number of crossings by exactly 1 .

Lemma 5.1.2. A crossing in a derived m-fence is either an end crossing or a middle crossing.

Proof. The definition of a derived $m$-fence implies that a crossing must involve two or three consecutive columns. If exactly three columns are involved, the same definition excludes any crossing aside from the end crossings. If exactly two columns are involved, the definition again excludes any crossing aside from the middle crossings.

Figure 5.2: The beginning of an untangle sequence starting at a 5 -fence. It is composed of derived 5 -fences.

Lemma 5.1.3. A flip changes a derived m-fence into another derived $m$-fence. In other words, the class of derived $m$-fences is closed under flip operations.

Proof. Lemma 5.1.2 ensures that we only have the following two cases. (i) The flip of an end crossing on the $w_{0}$ side $\left(w_{0} \in\{p, q\}\right)$ of the $k_{0}$-th column only changes statement 2 of the definition of a derived $m$-fence into statement 1 for $k, r=k_{0}, r_{0}$. The statements for the other $k, r$ are unchanged. (ii) The flip of a middle crossing simply leaves unchanged the statements for all $k, r$.

Figure 5.2 is actually a sequence of flips starting at an $m$-fence and it contains essentially all the possible cases (symmetries aside).

Lemma 5.1.4. A flip of a derived $m$-fence reduces its number of crossings by exactly 1 .
Proof. Let $S$ be a derived $m$-fence. Let $s_{1}$ and $s_{2}$ be two crossing segments of $S$. Let $s$ be any other segment of $S$. Let $s_{1}^{\prime}$ and $s_{2}^{\prime}$ be the two segments replacing $s_{1}$ and $s_{2}$ after they have been flipped, changing $S$ into $S^{\prime}$. We show that the number of crossings
between $s$ and $s_{1}, s_{2}$ is the same as between $s$ and $s_{1}^{\prime}, s_{2}^{\prime}$, ensuring that $S^{\prime}$ has exactly 1 crossing less than $S$.

Let us recall that, as for any convex matching, the number of crossings cannot increase (Lemma 3.2.3 [17]). The proof of this result consists of the analysis of the five possible typical convex matchings (symmetries aside) of the three segments $s_{1}, s_{2}, s$ (Figure 5.3). It is notable that only one of these five matchings, the one where each endpoint of $s$ lies in between two endpoints of $s_{1}, s_{2}$ of the same color, corresponds to an actual decrease in the number of crossings involving $s$ (the rightmost case in Figure 5.3).

Figure 5.3: The five convex positions of $s$ with respect to the flipping pair $s_{1}, s_{2}$ in the Bipartite version (the endpoints of the segment $s$ may be either red or blue). This is used in the proof of Lemma 5.1.4.

This crossing-destructive case cannot occur if two endpoints of $s_{1}, s_{2}$ of the same color are adjacent on the convex hull. Thus, Lemma 5.1.4 holds for flips of end crossings.

If $s_{1}, s_{2}$ is a middle crossing, then, by definition of a derived $m$-fence, no segment $s$ intersects both $s_{1}$ and $s_{2}$. Thus, the crossing-destructive case cannot occur, and Lemma 5.1.4 holds for flips of middle crossings.

Theorem 5.1.1 follows from Lemma 5.1.3 and Lemma 5.1.4.

### 5.2 Upper Bound for Convex Position

Let $P=C=\left\{p_{1}, \ldots, p_{|C|}\right\}$ be a set of points in convex position sorted in counterclockwise order along the convex hull boundary and consider a set of segments $S$ with endpoints $P$. Given a segment $p_{a} p_{b}$ and assuming without loss of generality that $a<b$, we define the crossing depth $\delta_{\times}\left(p_{a} p_{b}\right)$ as the number of points in $p_{a+1}, \ldots, p_{b-1}$ that are an endpoint of a segment in $S$ that crosses any other segment in $S$ (not necessarily $p_{a} p_{b}$ ). This definition is also in Chapter 3. We use the crossing depth to prove an $O(n \log n)$ bound in the Convex Multigraph version.

Theorem 5.2.1 ([31]). Consider a multiset $S$ of $n$ segments with endpoints $P=C$ in convex position.

In the Convex Multigraph version, there exists a removal strategy such that for any insertion strategy, the resulting untangle sequence of $S$ is of length $O(n \log |C|)=$ $O(n \log n)$.

In other words, we have the following upper bound:

$$
\mathrm{d}_{\text {Convex Multigraph }}^{\mathrm{R}}(n)=O(n \log |C|)=O(n \log n) .
$$

(a)

(b)

(c)

Figure 5.4: Proof of Theorem 5.2.1. (a) The segments of a convex multigraph are labeled with the crossing depth. (b,c) Two possible pairs of inserted segments, with one segment of the pair having crossing depth $\left\lfloor\frac{3}{2}\right\rfloor=1$.

Proof. We repeat the following procedure until there are no more crossings. Let $p_{a} p_{b} \in S$ be a segment with crossings (hence, crossing depth at least one) and $a<b$ minimizing $\delta_{\times}\left(p_{a} p_{b}\right)$ (Figure 5.4(a)). Let $q_{1}, \ldots, q_{\delta_{\times}\left(p_{a} p_{b}\right)}$ be the points defining $\delta_{\times}\left(p_{a} p_{b}\right)$ in order and let $i=\left\lceil\delta_{\times}\left(p_{a} p_{b}\right) / 2\right\rceil$. Since $p_{a} p_{b}$ has minimum crossing depth, the point $q_{i}$ is the endpoint of segment $q_{i} p_{c}$ that crosses $p_{a} p_{b}$. When flipping $q_{i} p_{c}$ and $p_{a} p_{b}$, we obtain a segment $s$ (either $s=q_{i} p_{a}$ or $s=q_{i} p_{b}$ ) with $\delta_{\times}(s)$ at most half of the original value of $\delta_{\times}\left(p_{a} p_{b}\right)$ (Figure 5.4(b, c)). Hence, this operation always divides the value of the smallest positive crossing depth by at least two. As the crossing depth is an integer smaller than $|C|$, after performing this operation $O(\log |C|)$ times, it produces a segment of crossing depth 0 . As the segments of crossing depth 0 can no longer participate in a flip, the claimed bound follows.

### 5.3 Upper Bound for Convex Trees

In this section, we prove the following linear upper bound in the Convex Tree version.
Theorem 5.3.1. Consider a set $S$ of $n$ segments with endpoints $P=C$ in convex position such that $(P, S)$ forms a tree.

In the Convex Tree version, for $n \geq 3$ there exists an untangle sequence of $S$ of length at most $3 n-8=O(n)$.

In other words, we have the following upper bound:

$$
\mathbf{d}_{\text {Convex Tree }}^{\mathrm{R}}(n) \leq 3 n-8=O(n) \quad \text { for } n \geq 3 .
$$

The proof of Theorem 5.3.1 has the same structure as the proof of Theorem 3.2.7. It relies on the following two lemmas.

Lemma 5.3.2. Consider a set $S$ of segments with endpoints $P$ such that $(P, S)$ forms a tree.

If there exists a segment $p_{a} p_{b} \in S$ and a point $q \in P$ of degree at least 2 such that all the segments of $S$ incident to $q$ cross the segment $p_{a} p_{b}$, then there exists a point $p_{c} \in P$ such that $q p_{c} \in S$ and such that the flip (in the Tree version) removing the segments $p_{a} p_{b}, q p_{c}$ inserts the segment $p_{a} q$.

Proof. Let $p_{d}$ be a point in $P$ such that $q p_{d} \in S$ and such that the flip (in the Tree version) removing the segments $p_{a} p_{b}, q p_{d}$ does not insert the segment $p_{a} q$. By definition
of a flip in the Tree version, the unique path $u_{q \rightarrow p_{a}}$ connecting $q$ to $p_{a}$ in the tree $(P, S)$ (before the flip) includes either none or both of the segments $p_{a} p_{b}, q p_{d}$ (to avoid forming a cycle with the inserted segments).

Case 1: $u_{q \rightarrow p_{a}}$ includes none. In the case where $u_{q \rightarrow p_{a}}$ includes none of the segments $p_{a} p_{b}, q p_{d}$, then let $q p_{c}$ be the first segment of $u_{q \rightarrow p_{a}}$ (starting at the point $q$ ). This segment $q p_{c}$ crosses the segment $p_{a} p_{b}$ by hypothesis. The path $u_{q \rightarrow p_{a}}$ includes the segment $q p_{c}$ but not the segment $p_{a} p_{b}$. Thus, by definition of a flip in the Tree version, the flip removing the segments $p_{a} p_{b}, q p_{c}$ inserts the segment $p_{a} q$.

Case 2: $u_{q \rightarrow p_{a}}$ includes both. In the case where $u_{q \rightarrow p_{a}}$ includes both of the segments $p_{a} p_{b}, q p_{d}$, then let $q p_{c}$ be any other segment adjacent to $q$. Such a segment exists since the point $q$ has degree at least 2 . The path $u_{q \rightarrow p_{a}}$ includes the segment $p_{a} p_{b}$ but not the segment $q p_{c}$. Thus, by definition of a flip in the Tree version, the flip removing the segments $p_{a} p_{b}, q p_{c}$ inserts the segment $p_{a} q$.

Lemma 5.3.3. Any set $S$ of $n$ segments with endpoints $P$ in convex position such that $(P, S)$ forms a tree admits an uncrossable segment $s \in S$ after at most 2 flips (in the Convex Tree version).

Proof. We assume that $S$ contains no segment of null crossing depth. Let $p_{1}, \ldots, p_{|P|}$ be the points of $P$ sorted in counterclockwise order along the convex hull boundary. Let $p_{a} p_{b} \in S(a<b)$ be a segment with crossings (hence, of crossing depth at least one) minimizing $\delta_{\times}\left(p_{a} p_{b}\right)$. Let $q_{1}, \ldots, q_{\delta_{\times}\left(p_{a} p_{b}\right)}$ be the points defining $\delta_{\times}\left(p_{a} p_{b}\right)$ sorted in counterclockwise order along the convex hull boundary. Since $p_{a} p_{b}$ has minimum positive crossing depth, and since we assume that $S$ contains no segment of null crossing depth, all the segments with at least one endpoint in $q_{1}, \ldots, q_{\delta_{\times}\left(p_{a} p_{b}\right)}$ cross the segment $p_{a} p_{b}$. We use 1 or 2 flips to insert one of the segments $q_{1} p_{a}, q_{\delta_{\times}\left(p_{a} p_{b}\right)} p_{b}$.

Case 1: using 1 flip. This case is defined as all the situations where one flip is enough to insert one of the segments $q_{1} p_{a}, q_{\delta_{x}\left(p_{a} p_{b}\right)} p_{b}$. Formally, there is nothing to prove. Note that, by Lemma 5.3.2, Case 1 covers all the situations where at least one of $q_{1}, q_{\delta_{\times}\left(p_{a} p_{b}\right)}$ has degree more than 1 .

Case 2: using 2 flips. This case is defined as the complement of Case 1. Therefore, both $q_{1}$ and $q_{\delta_{\times}\left(p_{a} p_{b}\right)}$ have degree exactly 1 . Let $p_{c} \in P$ (respectively $p_{d} \in P$ ) be the other endpoint of the segment adjacent to $q_{1}$ (respectively to $\left.q_{\delta_{\times}\left(p_{a} p_{b}\right)}\right)$. We choose to remove the segments $q_{1} p_{c}, p_{a} p_{b}$. By definition of Case 2, this flip inserts the segments $q_{1} p_{b}, p_{a} p_{c}$. We now choose to remove the segments $q_{1} p_{b}, q_{\delta_{\times}\left(p_{a} p_{b}\right)} p_{d}$. As the segment $q_{1} q_{\delta_{\times}\left(p_{a} p_{b}\right)}$ would not preserve the Tree property if inserted, this flip inserts the segment $q_{\delta_{\times}\left(p_{a} p_{b}\right)} p_{b}$ which has null crossing depth.

Proof of Theorem 3.2.11. For induction purpose, let $f(n)$ be the length of the untangle sequence of $S$ in the statement of Theorem 3.2.11 for $n$ segments.

If $n=3$, then $f(n)=1=3 n-8$.
If $n \geq 4$, and if $f(n-1) \leq 3(n-1)-8$, then, by Lemma 5.3.3, using at most 2 flips ensures that there exists at least one segment $s$ in $S$ contained in the boundary of the
convex hull of $P$. We invoke the induction hypothesis on the tree with $n-1$ segments obtained from $S$ by contracting the segment $s$ to a point. The resulting flip sequence also transforms $S$ into a tree where only the two segments adjacent to $s$ may cross. A final flip is enough to fully untangle $S$. The total number of flips use to untangle $S$ is

$$
f(n) \leq 3+f(n-1) \leq 3+3(n-1)-8=3 n-8,
$$

concluding the induction.

### 5.4 Upper Bound for One Point Inside or Outside a Convex

In this section, we prove Theorem 5.4.2, in which we assume that the multiset of segments to be untangled has no crossing pair of $C C$-segments (the segments with both endpoints in $C$ where $C$ is a subset of the endpoints which is in convex position), possibly after having untangled the $C C$-segments using one of the theorems of the Convex version. In the Cycle version (Theorem 3.2.7 [72] and Theorem 3.2.9 [85]) and in the Bipartite Matching version (Theorem 3.2.10 [18]), the preprocessing to untangle $C C$-segments takes $O(n)$ flips. However, in the Tree version (Theorem 3.2.11 [18]) and in general (Theorem 5.2.1 [31]), the best bound known is $O(n \log n)$. We first state a lemma used to prove Theorem 5.4.2.

Lemma 5.4.1 ([31]). Consider a set $C$ of points in convex position, and a multiset $S$ of $n$ crossing-free segments with endpoints in $C$. Consider the multiset $S \cup\{s\}$ where $s$ is an extra segment with one endpoint in $C$ and one endpoint $q$ anywhere in the plane.

In the $|\mathrm{T}|=1$ Multigraph version, there exists a removal strategy such that, for any insertion strategy, the resulting untangle sequence of $S \cup\{s\}$ is of length $O(n)$.

Proof. Iteratively flip the segment $s=q p_{1}$ with the segment $p_{2} p_{3} \in S$ crossing $q p_{1}$ the farthest from $q$. This flip inserts a $C C$-segment $p_{1} p_{2}$, which is impossible to flip again, because the line $p_{1} p_{2}$ is crossing free. The flip does not create any crossing between $C C$-segments of the multiset $S$.

We are now ready to state and prove the theorem.
Theorem 5.4.2 ([31]). Consider a multiset $S$ of $n$ segments with endpoints $P$ partitioned into $P=C \cup T$ where $C$ is in convex position, and $T=\{q\}$, and such that $S$ has no crossing pair of CC-segments (the segments with both endpoints in $C$ ), possibly after having untangled the CC-segments using one of the theorems of the Convex version. We define the parameter $t$ as the sum of the degrees of the points in $T$.

In the $|\mathrm{T}|=1$ Multigraph version, there exists a removal strategy such that for any insertion strategy, the resulting untangle sequence of $S$ is of length $O($ tn $)$.

In particular (using Theorem 5.2.1 to preprocess the CC-segments in $S$ ), we have the following upper bound:

$$
\mathbf{d}_{|\mathrm{T}|=1 \text { Multigraph }}^{\mathrm{R}}(n, t)=O(n \log |C|+t n)=O(n \log n+t n) .
$$

Proof. For each segment $s$ with endpoint $q$ with crossing, we apply Lemma 5.4.1 [31] to $s$ and the $C C$-segments in $S$ crossing $s$. Once a segment $s$ incident to $q$ is crossing free, it is impossible to flip it again as we fall in one of the following cases. Let $\ell$ be the line containing $s$.

Case 1: If $\ell$ is crossing free, then $\ell$ splits (see Lemma 2.6.1 [19, 31]) the multigraph in three partitions: the segments on one side of $\ell$, the segments on the other side of $\ell$, and the segment $s$ itself.

Case 2: If $\ell$ is not crossing free and $q$ is outside the convex hull of $C$, then $s$ is uncrossable (see the splitting lemma, i.e., Lemma 2.6.1 [19, 31]).

Case 3: If $q$ is inside the convex hull of $C$, then introducing a crossing on $s$ would require that $q$ lies in the interior of the convex quadrilateral whose diagonals are the two segments removed by a flip. The procedure excludes this possibility by ensuring that there are no crossing pair of $C C$-segments in $S$, and, therefore, that one of the removed segment already has $q$ as an endpoint.

Therefore, we need at most $n$ flips for each of the $t$ segments incident to $q$.

### 5.5 Upper Bound for One Point Inside and One Point Outside a Convex

Given an endpoint $p$, let $d^{\circ}(p)$ denote the degree of $p$, that is, the number of segments incident to $p$. The following lemma is used to prove Theorem 5.5.2.
Lemma 5.5.1. Consider a multiset $S$ of $n$ segments with endpoints $P$ partitioned into $P=C \cup T$ where $C$ is in convex position, and $T=\left\{q, q^{\prime}\right\}$ such that $q$ is outside the convex hull of $C$ and $q^{\prime}$ is inside the convex hull of $C$. Consider that $q$ is the endpoint of a single segment $s$ in $S$ and that all the crossings of $S$ are on $s$. We define the parameter $t$ as the sum of the degrees of the points in $T$, i.e., $t=d^{\circ}\left(q^{\prime}\right)+1$.

In the Inout Multigraph version, there exists a removal strategy such that, for any insertion strategy, the resulting flip sequence starting at $S$ is of length $O($ tn $)$ and ends with a multiset of segments where with all crossings (if any) are on the segment qq' (if $q q^{\prime} \notin S$ then there are no crossings).
Proof. We proceed as follows, while $s$ has crossings. For induction purpose, let $f(n)$ be the length of the flip sequence in the lemma statement for $n$ segments. Let $s^{\prime}$ be the segment that crosses $s$ at the point farthest from $q$. We flip $s$ and $s^{\prime}$, arriving at one of the three cases below (Figure 5.5).

Case 1

Case 2

Case 3

Figure 5.5: The three cases in the proof of Lemma 5.5.1.

Case $1(\mathbf{C T} \times \mathbf{C C})$. In this case, the segment $s^{\prime}$ is a $C C$-segment. Notice that the line $\ell$ containing $s^{\prime}$ becomes crossing free after the flip. There are segments on both sides of $\ell$. If $\ell$ separates $q, q^{\prime}$, then we untangle both sides independently (see the splitting lemma, i.e., Lemma 2.6.1 [19, 31]) using $O(n)$ and $O(t n)$ flips (Theorem 5.4.2). Otherwise, the segments on one side of $\ell$ are already crossing free (because of the specific choice of $s^{\prime}$ ) and we inductively untangle the $n^{\prime} \leq n-1$ segments on the other side of $\ell$ using $f\left(n^{\prime}\right)$ flips.

Case $2(\mathbf{C T} \times \mathbf{C T} \rightarrow \mathbf{C C}, \mathbf{T T})$. If $s^{\prime}$ is a $C T$-segment and one of the inserted segments is the $T T$-segment $q q^{\prime}$, then the procedure is over as all crossings are on $q q^{\prime}$.

Case 3 ( $\mathbf{C T} \times \mathbf{C T} \rightarrow \mathbf{C T}, \mathbf{C T}$ ). In this case two $C T$-segments are inserted. Let $p \in C$ be an endpoint of $s=q p$. Since the inserted $C T$-segment $q^{\prime} p$ is crossing free, Case 3 only happens $O(t)$ times before we arrive at Case 1 or Case 2 .

Putting the three cases together, we obtain the recurrence

$$
f(n) \leq O(t)+f\left(n^{\prime}\right), \text { with } n^{\prime} \leq n-1,
$$

which solves to $f(n)=O(t n)$, as claimed.
We are now ready to prove the theorem.
Theorem 5.5.2 ([31]). Consider a multiset $S$ of $n$ segments with endpoints $P$ partitioned into $P=C \cup T$ where $C$ is in convex position, and $T=\left\{q, q^{\prime}\right\}$ such that $q$ is outside the convex hull of $C$ and $q^{\prime}$ is inside the convex hull of $C$. We define the parameter $t$ as the sum of the degrees of the points in $T$, i.e., $t=d^{\circ}(q)+d^{\circ}\left(q^{\prime}\right)$.

In the Inout Multigraph version, there exists a removal strategy such that for any insertion strategy, the resulting untangle sequence of $S$ is of length $O\left(d^{\circ}(q) d^{\circ}\left(q^{\prime}\right) n+\right.$ $\left.d_{\text {conv }}(n)\right)=O\left(t^{2} n+d_{\text {conv }}(n)\right)$, where $d_{\text {conv }}(n)$ is the number of fips to untangle any multiset of at most $n$ segments with endpoints in convex position.

In particular (using Theorem 5.2.1 for $d_{\text {conv }}(n)$ ), we have the following upper bound:

$$
\mathbf{d}_{\text {Inout Multigraph }}^{\mathrm{R}}(n, t)=O\left(d^{\circ}(q) d^{\circ}\left(q^{\prime}\right) n+n \log n\right)=O\left(t^{2} n+n \log n\right) .
$$

Proof. The untangle sequence contains four phases.
Phase $1(\mathbf{C C} \times \mathbf{C C})$. In this phase, we remove all crossings between pairs of $C C$-segments in $S$ using $d_{\text {conv }}(n)$ flips. Throughout all the phases, the invariant that no pair of $C C$-segments in $S$ crosses is preserved.

Phase $2\left(\mathbf{C q}^{\prime} \times \mathbf{C C}\right)$. In this phase, we remove all crossings between pairs composed of a $C C$-segment and a $C T$-segment incident to $q^{\prime}$ (the point inside the convex hull of $C)$ using $O(t n)$ flips by Theorem 5.4.2.

Phase 3 (Cq). At this point, all crossings involve a segment incident to $q$. In this phase, we deal with all remaining crossings except the crossings involving the segment $q q^{\prime}$. The splitting lemma (Lemma 2.6.1 [19, 31]) allows us to remove the crossings in each $C T$-segment $s$ incident to $q$ independently, which we do using $O\left(d^{\circ}\left(q^{\prime}\right) n\right)$ flips using Lemma 5.5.1. As there are $d^{\circ}(q) C T$-segments adjacent to $q$ in $S$, the total number of flips is $O\left(d^{\circ}(q) d^{\circ}\left(q^{\prime}\right) n\right)=O\left(t^{2} n\right)$.

Phase $4(\mathbf{C C} \times \mathbf{T T})$. At this point, all crossings involve the $T T$-segment $q q^{\prime}$. The endpoints in $C$ that are adjacent to segments with crossings, together with $q^{\prime}$, are all in convex position. Hence, the only endpoint not in convex position is $q$, and we apply Theorem 5.4.2 using $O(t n)$ flips.

After the $d_{\text {conv }}(n)$ flips in Phase 1, the number of flips is dominated by Phase 3 with $O\left(d^{\circ}(q) d^{\circ}\left(q^{\prime}\right) n\right)=O\left(t^{2} n\right)$ flips.

Notice that, in certain cases (for example in the red-blue case with $q, q^{\prime}$ having different colors) a flip between two $C T$-segments never produces two $C T$-segments. Consequently, Case 3 of the proof of Lemma 5.5.1 never happens, and the bound in Theorem 5.5.2 decreases to $O\left(d_{\text {conv }}(n)+t n\right)$.

### 5.6 Upper Bound for Two Points Inside a Convex

We prove a similar theorem for two points inside the convex hull of $C$.
Theorem 5.6.1 ([31]). Consider a multiset $S$ of $n$ segments with endpoints $P$ partitioned into $P=C \cup T$ where $C$ is in convex position, and $T=\left\{q, q^{\prime}\right\}$ such that $q$ and $q^{\prime}$ are inside the convex hull of $C$. We define the parameter $t$ as the sum of the degrees of the points in $T$.

In the Inin Multigraph version, there exists a removal strategy such that for any insertion strategy, the resulting untangle sequence of $S$ is of length $O\left(t n+d_{\text {conv }}(n)\right)$, where $d_{\text {conv }}(n)$ is the number of flips to untangle any multiset of at most $n$ segments with endpoints in convex position.

In particular (using Theorem 5.2.1 for $d_{\text {conv }}(n)$ ), we have the following upper bound:

$$
\mathbf{d}_{\text {Inin Multigraph }}^{\mathrm{R}}(n, t)=O(t n+n \log n) .
$$

Proof. The untangle sequence is decomposed in five phases. At the end of each phase, a new type of crossings is removed, and types of crossings removed in the previous phases are not present, even if they may temporarily appear during the phase.

Phase $1(\mathbf{C T} \times \mathbf{C T})$. In this phase, we remove all crossings between pairs of $C T$-segments in $S$ using $O\left(d_{\text {conv }}(t)\right)=O\left(d_{\text {conv }}(n)\right)$ flips. We separately solve two convex sub-problems defined by the $C T$-segments in $S$, one on each side of the line $q q^{\prime}$.

Phase $2(\mathbf{C C} \times \mathbf{C C})$. In this phase, we remove all crossings between pairs of $C C$-segments in $S$ using $O\left(d_{\text {conv }}(n)\right)$ flips. As no $C T$-segment has been created, there is still no crossing between a pair of $C T$ segments. Throughout, our removal will preserve the invariant that no pair of $C C$-segments in $S$ crosses.

Phase 3 (CT $\times$ non-central CC). We distinguish between a few types of $C C$ segments. The central $C C$-segments cross the segment $q q^{\prime}$ (regardless of $q q^{\prime}$ being in $S$ or not), while the non-central do not. The peripheral $C C$-segments cross the line $q q^{\prime}$ but not the segment $q q^{\prime}$, while the outermost $C C$-segments do not cross either. In this phase, we remove all crossings between $C T$-segments in $S$ and non-central $C C$-segments in $S$.

Given a non-central $C C$-segment $p p^{\prime}$, let the out-depth of the segment $p p^{\prime}$ be the number of points of $C$ that are contained inside the halfplane bounded by the line $p p^{\prime}$ and not containing $T$. Also, let $\chi$ be the number of crossings between the non-central
$C C$-segments and the $C T$-segments in $S$. At the end of each step the two following invariants are preserved. (i) No pair of $C C$-segments in $S$ crosses. (ii) No pair of $C T$-segments in $S$ crosses.

At each step, we choose to flip a non-central $C C$-segment $p p^{\prime}$ of minimum out-depth that crosses a $C T$-segment. We flip $p p^{\prime}$ with the $C T$-segment $q^{\prime \prime} p^{\prime \prime}$ (with $q^{\prime \prime} \in\left\{q, q^{\prime}\right\}$ ) that crosses $p p^{\prime}$ at the point closest to $p$ (Figure 5.6(a) and Figure 5.7(a)). One of the possibly inserted pairs may contain a $C T$-segment $s$ that crosses another $C T$-segment $s^{\prime}$, violating the invariant (ii) (Figure 5.6(b) and Figure 5.7(b)). If there are multiple such segments $s^{\prime}$, then we consider $s^{\prime}$ to be the segment whose crossing with $s$ is closer to $q^{\prime \prime}$. We flip $s$ and $s^{\prime}$ and obtain either two $C T$-segments (Figure 5.6(c) and Figure 5.7(c)) or a $C C$-segment and the segment $q q^{\prime}$ (Figure 5.6(d) and Figure 5.7(d)). The analysis is divided in two main cases.

Figure 5.6: Theorem 5.6.1, Phase 3 when $p p^{\prime}$ is an outermost segment.
If $p p^{\prime}$ is an outermost $C C$-segment (see Figure 5.6), then case analysis shows that the two invariants are preserved and $\chi$ decreases.

(a)

(b)

(c)

(d)

Figure 5.7: Theorem 5.6.1, Phase 3 when $p p^{\prime}$ is a peripheral segment.
If $p p^{\prime}$ is a peripheral $C C$-segment (see Figure 5.7), then a case analysis shows that the two invariants are preserved and $\chi$ has the following behavior. If no $C C$-segment is inserted, then $\chi$ decreases. Otherwise a $C C$-segment and a $T T$-segment are inserted and $\chi$ may increase by $O(t)$ (Figure $5.7(\mathrm{~d})$ ). Notice that the number of times the $T T$-segment $q q^{\prime}$ is inserted is $O(t)$, which bounds the total increase by $O\left(t^{2}\right)$.

As $\chi=O(t n)$, the total increase is $O\left(t^{2}\right)$, and $\chi$ decreases at all but $O(t)$ steps, we have that the number of flips in Phase 3 is $O(t n)$.

Phase $4\left(\mathbf{C T} \times \mathbf{C C}_{\text {central }}\right)$. At this point, each crossing involves a central $C C$ segment and either a $C T$-segment or the $T T$-segment $q q^{\prime}$. In this phase, we remove all crossings between $C T$-segments and central $C C$-segments in $S$, ignoring the $T T$ segments. This phase ends with crossings only between $q q^{\prime}$ and central $C C$-segments in $S$.

Figure 5.8: Theorem 5.6.1, Phase 4. (a) A pair of $C T$-segments with an ear. (b) A $C C$-segment and a $C T$-segment with an ear. (c) Flipping an ear that produces crossing pairs of $C T$-segments. (d) Flipping an ear that inserts a non-central $C C$-segment with crossings.

Given four endpoints $q^{\prime \prime} \in T, p, p^{\prime \prime} \in C$, and $x \in C \cup T$, we say that a pair of segments $p^{\prime \prime} q^{\prime \prime}, x p \in S$ crossing at a point $o$ contains an ear $\widehat{p p^{\prime \prime}}$ if the interior of the triangle $p p^{\prime \prime} o$ intersects no segment of $S$ (see Figure 5.8(a) and 5.8(b)). Every set of segments with endpoints in $C \cup T$ with $|T|=2$ that has crossings (not involving the $T T$-segment) contains an ear (adjacent to the crossing that is farthest from the line $\left.q q^{\prime}\right)$.

At each step, we flip a pair of segments $p^{\prime \prime} q^{\prime \prime}, x p$ that contains an ear $\widehat{p^{\prime \prime}}$, prioritizing pairs where both segments are $C T$-segments. Notice that, even though initially we did not have crossing pairs of $C T$-segments in $S$, they may be produced in the flip (Figure 5.8(c)). If the flip inserts a non-central $C C$-segment which crosses some $C T$ segments in $S$ (Figure 5.8(d)), then, we perform the following while loop. Assume without loss of generality that $q q^{\prime}$ is horizontal and $s$ is closer to $q^{\prime}$ than to $q$. While there exists a non-central $C C$-segment $s$ with crossings, we flip $s$ with the $C T$-segment $s^{\prime}$ crossing $s$ that comes first according to the following order. As a first criterion, a segment incident to $q$ comes before a segment incident to $q^{\prime}$. As a second tie-breaking criterion, a segment whose crossing point with $s$ that is farther from the line $q q^{\prime}$ comes before one that is closer.

Let $\chi=O(t n)$ be the number of crossings between central $C C$-segments and $C T$ segments in $S$ plus the number of crossings between $C T$-segments in $S$. A case analysis shows that the value of $\chi$ decreases at each step. If no non-central $C C$-segment is inserted, then the corresponding step consists of a single flip. As $\chi$ decreases, there are $O(t n)$ steps that do not insert a non-central $C C$-segment.

However, if a non-central $C C$-segment is inserted, at the end of the step we inserted a $C C$-segment that is uncrossable (see the splitting lemma, i.e., Lemma 2.6.1 [19, 31]). As the number of $C C$-segments in $S$ is $O(n)$, we have that the number of times the while loop is executed is $O(n)$. Since each execution of the while loop performs $O(t)$ flips, we have a total of $O(t n)$ flips in this phase.

Phase $5\left(\mathbf{T T} \times \mathbf{C C}_{\text {central }}\right)$. In this phase, we remove all crossings left, which are between the possibly multiple copies of the $T T$-segment $q q^{\prime}$ and central $C C$-segments in $S$. The endpoints of the segments with crossings are in convex position and all other endpoints are outside their convex hull. Hence, by the splitting lemma (Lemma 2.6.1 [19, 31]), it is possible to obtain a crossing-free multigraph using $O\left(d_{\text {conv }}(n)\right)$ flips.

### 5.7 Upper Bound for Two Points Outside a Convex

In this section, we prove a theorem with a bound that is quadratic in $t$. In fact, it appears that this bound is exactly the same as in Theorem 5.5.2.

Theorem 5.7.1 ([31]). Consider a multiset $S$ of $n$ segments with endpoints $P$ partitioned into $P=C \cup T$ where $C$ is in convex position, and $T=\left\{q, q^{\prime}\right\}$ such that $q$ and $q^{\prime}$ are outside the convex hull of $C$. We define the parameters $d^{\circ}(q), d^{\circ}\left(q^{\prime}\right)$ as the degrees of $q, q^{\prime}$, and $t$ as the $\operatorname{sum} d^{\circ}(q)+d^{\circ}\left(q^{\prime}\right)$.

In the Outout Multigraph version, there exists a removal strategy such that for any insertion strategy, the resulting untangle sequence of $S$ is of length $O\left(d^{\circ}(q) d^{\circ}\left(q^{\prime}\right) n+\right.$ $\left.d_{\text {conv }}(n)\right)=O\left(t^{2} n+d_{\text {conv }}(n)\right)$, where $d_{\text {conv }}(n)$ is the number of fips to untangle any multiset of at most $n$ segments with endpoints in convex position.

In particular (using Theorem 5.2.1 for $d_{\text {conv }}(n)$ ), we have the following upper bound:

$$
\mathbf{d}_{\text {Outout Multigraph }}^{\mathrm{R}}(n, t)=O\left(t^{2} n+n \log n\right)
$$

Figure 5.9: Illustrations for the proof of Theorem 5.7.1. (a) Phase 2. (b) Phase 3.1. (c) \& (d) Beginning of Phase 3.2. (e) Phase 3.2.1. (f) \& (g) Ending of Phase 3.2. (h) Phase 3.3.

Proof. Throughout this proof, we say that a $T T$-segment (respectively a $C T$-segment) is a $T T_{\mathrm{in}}$-segment (respectively $C T_{\mathrm{in}}$-segment) if it intersects the interior of the convex hull of $C$ and a $T T_{\text {out }}$-segment (respectively $C T_{\text {out }}$-segment) otherwise. Without loss of generality, we assume that $q^{\prime}$ is not in the interior of the convex hull of $C \cup\{q\}$. Next, we describe a removal strategy.

Phase 1: preprocessing using at most $n d^{\circ}\left(q^{\prime}\right)+d_{\text {conv }}(n)$ flips. To begin, we remove from $S$ all the segments incident to $q$ (recall that $q$ is not an arbitrary point of $T$ as $q^{\prime}$ is not in the interior of the convex hull of $C \cup\{q\}$ ). By Theorem 5.4.2 [31], we use at most $n d^{\circ}\left(q^{\prime}\right)+d_{\text {conv }}(n)$ flips to untangle $S$. We now add one by one the segments incident to $q$ back to $S$. Each time we add a segment $s$ incident to $q$, we untangle $S$ using at most $n d^{\circ}\left(q^{\prime}\right)$ flips via the removal strategy described next.

Phase 2: untangling the $T T$-segment $q q^{\prime}$ using at most $n$ flips. In this paragraph, we describe a removal strategy to untangle $S$ in the case where all the crossings are on the segment $q q^{\prime}$ (Figure 5.9(a)). This case arises when the segment $s$ we add back to $S$ happens to be $q q^{\prime}$, or when the segment $q q^{\prime}$ is inserted by a flip and the other inserted segment is crossing free.

If $q q^{\prime}$ is not already crossing free, we flip $q q^{\prime}$ with any segment, say $p p^{\prime}$. Next, we present how we use the splitting lemma (Lemma 2.6.1 [19, 31]) to remove from $S$ all the $C T$-segments except the two freshly inserted segments. If $S$ already contains a copy of one of two freshly inserted segments before the flip, then this segment remains crossing free after the flip with no need for further untangling. In the following, we assume without loss of generality that $S$ contains no extra copies of the two freshly inserted segments and that the line $q q^{\prime}$ is horizontal.

Because the segment $q q^{\prime}$ (not necessarily in $S$ ) intersects the convex hull of $C$, each crossing-free $C T_{\text {out-segment }} S$ is uncrossable, and we thereby remove it form $S$ by the splitting lemma (Lemma 2.6.1 [19, 31]). Next, we describe one iteration of how we also remove the crossing-free $C T_{\mathrm{in}}$-segments of $S$ by consecutive use of the splitting lemma (Lemma 2.6.1 [19, 31]). Among all the points in $C$ above the line $q q^{\prime}$ which are endpoints of some crossing-free $C T_{\mathrm{in}}$-segment, let $p_{\text {top }}$ be one of the topmost ones. Let $q_{\text {top }}$ be a point of $T$ connected to $p_{\text {top }}$ by a segment of $S$. The line $p_{\text {top }} q_{\text {top }}$ is crossing free, and the only segments of $S$ with crossings are on the same side of the line $p_{\text {top }} q_{\text {top }}$ as the segment $q q^{\prime}$ (not necessarily in $S$ ). Thus, by the splitting lemma (Lemma 2.6.1 [19, 31]) again, we remove from $S$ the segment $p_{\text {top }} q_{\text {top }}$ (and all its possible copies) together with all the segments of $S$ which are not on the same side of the line $p_{\text {top }} q_{\text {top }}$ as the segment $q q^{\prime}$.

After all this removal of $C T$-segments, the line $p p^{\prime}$ is crossing free with $q$ on side and $q^{\prime}$ on the other side. By the splitting lemma (Lemma 2.6.1 [19, 31]), we untangle the segments of $S$ on each side of the line $p p^{\prime}$ separately. By Theorem 5.4.2 [31], we use at most $n-1$ flips to untangle both sides (the -1 comes from the disappearance of the $C C$-segment $p p^{\prime}$ after the first flip of this phase). In total, this phase uses at most $n$ flips.

Phase 3: untangling a $C T$-segment $p q$ using at most $n d^{\circ}\left(q^{\prime}\right)$ flips. In this paragraph, we describe a removal strategy to untangle $S$ in the case where all the crossings are on a segment $p q$. This case arises when the segment $s$ we add back to $S$ is a $C T$-segment, or when a $C T$-segment is inserted by a flip. Next we present the three sub-phases of Phases 3. We prove that one call to Phase 3.1 uses at most $n$ flips, that one call to Phase 3.3 also uses at most $n$ flips, and that one call to Phase 3.2 removes (by splitting) as many $C T$-segments incident to $q^{\prime}$ from $S$ as the number of flips performed in this one call of Phase 3.2.

Phase 3.1: at most $n$ consecutive $C T \times C C$ flips. In this paragraph, we describe Phase 3.1 of the removal strategy (Figure 5.9(b)).

While $s^{\prime}$, the segment of $S$ that crosses $s$ the farthest away from $q$, is a $C C$-segment, we flip $s$ and $s^{\prime}$ and we set $s$ to be the newly inserted segment incident to $q$. By Lemma 5.4.1 [31], at most $n$ flips are performed in this loop.

At the end of Phase 3.1, exactly one following two alternatives holds.

- $s$ is crossing free, ending Phase 3.
- $s^{\prime}$ is adjacent to $q^{\prime}$ and we go to Phase 3.2.

Phase 3.2: consecutive $C T \times C T$ flips splitting away as many $C T$-segments. In this paragraph, we describe Phase 3.2 of the removal strategy (Figures 5.9(c), (d), (e), (f), (g)).

While $s \neq q q^{\prime}$ and while $s^{\prime}$, the segment of $S$ that crosses $s$ the farthest away from $q$, is a $C T$-segment, we do the following.

- Let $o$ be the intersecting point between the segments $s=q p$ and $s^{\prime}=q^{\prime} p^{\prime}$.
- We flip $s$ and $s^{\prime}$.
- If the segment $q^{\prime} p$ is inserted, we call Phase 3.2.1 described hereafter resulting in a situation where all the crossings of $S$ are on the segment $q p^{\prime}$.
- We set $s$ to be $q p^{\prime}$, the newly inserted segment incident to $q$.

The number of segments incident to $q^{\prime}$ initially crossing the segment $s$ upper bounds the number of consecutive loops.

At the end of Phase 3.2, exactly one following three alternatives holds.

- $s=q p^{\prime}$ and $s$ is crossing free, ending Phase 3.
- $s=q p^{\prime}, s^{\prime}$ is a $C C$-segment and we go back to Phase 3.1 after having split away (using the splitting lemma: Lemma 2.6.1 [19, 31]) all the segments of $S$ which lie on the same side of the line $q^{\prime} p^{\prime}$ as $p$. This include all the segments which have been inserted during this call of Phase 3.2. For Lemma 2.6.1 [19, 31] to apply, we prove that the line $q^{\prime} p^{\prime}$ is crossing free. Let $o_{1}$ be the crossing point between $s=q p^{\prime}$ and $s^{\prime}$. We assume that the line $q^{\prime} p^{\prime}$ is not crossing free and derive a contradiction. If the line $q^{\prime} p^{\prime}$ crosses a $C C$-segment at a point $o_{2}$, then $p^{\prime}$ is in the interior of the triangle $o_{1} o_{2} p$ (Figure 5.9(f)). If the line $q^{\prime} p^{\prime}$ crosses a $C T$-segment $q p_{1}$, then $p^{\prime}$ is in the interior of the triangle $o_{1} p_{1} p$ (Figure 5.9(g)). Both cases contradicts the fact that $p^{\prime} \in C$.
- $s=q q^{\prime}$ and we go to Phase 3.3.

Phase 3.2.1: untangling the segment $q^{\prime} p$ using at most $n$ flips. In this paragraph, we describe a removal strategy using the splitting lemma to untangle a subset $S^{\prime \prime}$ of $S$ where all the crossings are on the segment $q^{\prime} p$ (Figures 5.9(c), (d), (e)). This case arises specifically in Phase 3.2.

In the case where the segment $q^{\prime} p$ is not crossing free, we define $S^{\prime}$ as the segments of $S$ in the quadrant defined by the rays from $o$ and directed by the vectors $\overrightarrow{o q^{\prime}}$ and $\overrightarrow{o p}$. Strictly speaking, we do not apply the splitting lemma (Lemma 2.6.1 [19, 31]). However, next we show that both of these rays are crossing free, proving that untangling $S^{\prime}$ does not affect the segments in $S \backslash S^{\prime}$.

Recall that, since we have assumed that $q^{\prime}$ is not in the interior of the convex hull of $C \cup\{q\}$, and since the segment $q^{\prime} p^{\prime}$ is crossing free, the ray from $o$ and directed by the vector $\overrightarrow{o q^{\prime}}$ is crossing free. Next, we show that the ray from $o$ and directed by the vector $\overrightarrow{o p}$ is also crossing free.

Since the segment $q^{\prime} o($ not in $S$ ) is crossing free, no segment of $S$ incident to $q$ crosses the segment $q^{\prime} p^{\prime}$. Therefore, at least one $C C$-segment of $S$ crosses the segment $q^{\prime} p$ at a point we call $o_{3}$.

We assume that the ray from $o$ and directed by the vector $\overrightarrow{o p}$ is not crossing free and derive a contradiction. If a $C C$-segment crosses the ray from $o$ and directed by the vector $\overrightarrow{o p}$ at a point $o_{4}$, then $p$ is in the interior of the triangle $o_{3} o_{4} p^{\prime}$ (Figure 5.9(c)). If a $C T$-segment $p_{2} q^{\prime}$ crosses the ray from $o$ and directed by the vector $\overrightarrow{o p}$, then $p$ is in the interior of the triangle $o_{3} p_{2} p^{\prime}$ (Figure 5.9(d)). Both cases contradicts the fact that $p \in C$.

Phase 3.3: ending Phase 3 after insertion of the $T T$-segment using at most $n$ flips. In this paragraph, we describe the removal strategy in the case where the $T T$-segment $q q^{\prime}$ and a $C C$-segment, say $p p^{\prime}$, are inserted (Figure 5.9(h)). For the segment $p p^{\prime}$ to have crossings, at least one point of $P$ has to be in the interior of the triangle $p p^{\prime} o$.

If one point, say $o_{5}$, of the $T T$-segment $q q^{\prime}$ is in the interior of the convex hull of $C$, then, by convexity the interior of the triangle $p p^{\prime} O_{5}$ does not contain any point of $P$. The triangle $p p^{\prime} o_{5}$ contains the triangle $p p^{\prime} o$, and the segments $o p$ and $o p^{\prime}$ are crossing free. Therefore, by the triangle argument (i.e. Lemma 2.4.1), the $C C$-segment $p p^{\prime}$ is crossing free. In this case, we go through Phase 2 to untangle $S$ using at most $n$ flips.

If the $T T$-segment $q q^{\prime}$ does not intersects the interior of the convex hull of $C$, then the $T T$-segment $q q^{\prime}$ is crossing free. In this case, all the crossings of $S$ involve the $C C$-segment $p p^{\prime}$ and another $C C$-segment. By a similar induction as in the proof of Theorem 3.2.12 [19], we untangle $S$ using at most $n$ flips.

At the end of Phase 3.3, after having used at most $n$ flips, $S$ is crossing free, ending Phase 3.

We now sum up the total number of flips performed in one call of Phase 3. The total number of flips used in all the calls to Phase 3.2 is at most $n d^{\circ}\left(q^{\prime}\right)$, and the total number of flips in Phase 3 is at most $2 n\left(d^{\circ}\left(q^{\prime}\right)+2\right.$ ) (it is possible to prove $n\left(d^{\circ}\left(q^{\prime}\right)+1\right)$ ).

Total number of flips used in all the phases. Phase 1 uses at most $n d^{\circ}\left(q^{\prime}\right)+d_{\text {conv }}(n)$ flips and is called once. Phase 2 uses at most $n$ flips and is called at most once. Phase 3 uses at most $2 n\left(d^{\circ}\left(q^{\prime}\right)+2\right)$ flips and is called at most $d^{\circ}(q)$ times. The total number of
flips used in all the phases is at most $n d^{\circ}\left(q^{\prime}\right)+d_{\text {conv }}(n)+n+2 n\left(d^{\circ}\left(q^{\prime}\right)+2\right) d^{\circ}(q)$ which is $O\left(d^{\circ}(q) d^{\circ}\left(q^{\prime}\right) n+d_{\text {conv }}(n)\right)$.

### 5.8 Upper Bound for Red-on-a-Line Matchings

In this section, we prove the following upper bound.
Theorem 5.8.1 ([33]). Consider a set $S$ of $n$ segments with endpoints $P$ partitioned into $n$ red points and $n$ blue points such that the red points lie on the $x$-axis, such that the blue points lie above the $x$-axis, and such that $(P, S)$ forms a bipartite matching.

In the Redonaline Matching version, there exists an untangle sequence of $S$ of length at most $\binom{n}{2}=O\left(n^{2}\right)$.

In other words, we have the following upper bound:

$$
\mathbf{d}_{\text {Redonaline Matching }}^{\mathrm{R}}(n) \leq\binom{ n}{2}=O\left(n^{2}\right)
$$

The proof consists of the analysis of the number of flips performed by the recursive algorithm described next. This analysis is based on a novel approach called state tracking. State tracking is in fact not specific to the red-on-a-line case, which is why Lemma 5.8.2 is stated and proven in the non-bipartite setting. Lemma 5.8.2 is then used in the red-on-a-line case to prove Lemma 5.8.3, which in turn is used to prove Theorem 5.8.1. Lemma 5.8.2 also provides an alternative proof of the well-known Theorem 3.2.2 [17], which we present at the end of this section.

Throughout, we assume general position (no two blue points with the same $y$ coordinate). Let the top segment of a red-on-a-line matching be the segment with the topmost blue endpoint (Figure 5.10(a)).

Figure 5.10: (a) A red-on-a-line matching with $s_{1}$ as the top segment. (b) The matching just before the first recursive calls of the algorithm, where $s_{1}$ is uncrossable.

Algorithm. While the top segment $s_{1}$ of the matching crosses another segment $s_{2}$, we flip $s_{1}$ and $s_{2}$. If multiple segments cross $s_{1}$, then we choose $s_{2}$ as the top segment among the segments crossing $s_{1}$.

The previous loop stops when the top segment $s_{1}$ has no crossings. At this point, we have that $s_{1}$ splits (Lemma 2.6.1 $[19,31]$ ) the matching into at most two non-empty submatchings, one to each side of $s_{1}$. We recursively call the algorithm on these submatchings (Figure 5.10(b)).

Flip Complexity. The analysis of the number of flips performed by the algorithm stems from the following observations. We define three possible states for a pair of segments (Figure 5.11).

- State X: the segments are crossing.
- State H: the segments are not crossing and their endpoints are in convex position.
- State $\mathbf{T}$ : the endpoints are not in convex position.

Figure 5.11: The three different states of pairs of segments.
In the convex case, there are no $\mathbf{T}$-states and a flip increases the number of $\mathbf{H}$-pairs by at least 1 , and decreases the number of $\mathbf{X}$-pairs as well. Hence, counting either $\mathbf{X}$ or H-pairs yields the $\binom{n}{2}$ upper bound on $\mathbf{d}_{\text {Convex Multigraph }}^{\natural}(n)$ (see below the alternative proof of Theorem 3.2.2 [17]). However, when the points are not in convex position, counting $\mathbf{H}$ and $\mathbf{X}$-pairs is fundamentally different. We will see that counting $\mathbf{H}$-pairs is more useful to prove the desired bounds.

When the points are not in convex position, a flip may decrease the number of H-pairs. Figure 5.12 shows two such situations where flipping $s_{1}, s_{2}$ does not increase the number of $\mathbf{H}$-pairs. There is one $\mathbf{H}$-pair involving segment $s$ before the flip, and none after the flip. Notice that, if we added multiple segments close to $s$, the number of $\mathbf{H}$-pairs would actually decrease. However, the algorithm avoids these situations by choosing to flip top segments. The full proof involves state tracking, a novel approach to analyze flip sequences, which is described next.

Figure 5.12: Two cases where flipping $s_{1}, s_{2}$ does not increase the number of $\mathbf{H}$-pairs. The upper cone of $s_{1}, s_{2}^{\prime}$ is shaded.

State Tracking. We have $\binom{n}{2}$ pairs of segments before and after a flip. Each pair has an associated state. However, since two segments change in the matchings, there is no clear correspondence between the state of each pair before and after the flip. State tracking establishes this correspondence by making choices of which pair of segments in the initial matching corresponds to which pair of segments in the resulting matching. These choices are performed deliberately to obtain certain state transitions instead of others and prove the desired bounds.

The following notations will be used throughout the rest of this section and are summarized in Figure 5.13. Let $r_{1}, r_{2}$ be two red points and $b_{1}, b_{2}$ be two blue points. Let $s_{1}, s_{2}, s_{1}^{\prime}, s_{2}^{\prime}$ be the following four segments respectively: $r_{1} b_{1}, r_{2} b_{2}, r_{1} b_{2}, r_{2} b_{1}$. We consider a flip that replaces the pair of segments $s_{1}, s_{2}$ by $s_{1}^{\prime}, s_{2}^{\prime}$. Let $S$ denote the matching before the flip and $S^{\prime}$ denote the resulting matching after the flip.

Figure 5.13: Notations for a generic flip and for a variable segment $s$.
We order the $\binom{n}{2}$ pairs of segments of $S$ in a column vector. There are three types of pairs of segments in $S$ with respect to the flip: the unaffected pairs (involving neither $s_{1}$ nor $s_{2}$ ), the flipping pair $s_{1}, s_{2}$, and the affected pairs (involving exactly one of $s_{1}$ or $s_{2}$ ). We choose the new order of the $\binom{n}{2}$ pairs of segments of $S^{\prime}$ in a way that satisfies the following properties with respect to the previous vector. The unaffected pairs keep the same indices. The pair $s_{1}^{\prime}, s_{2}^{\prime}$ gets the index of $s_{1}, s_{2}$. Next, we describe the remaining indices.

Let $s$ be a segment of $S$ distinct from $s_{1}$ and $s_{2}$. Let $r$ and $b$ be the red and blue endpoints of $s$. Let $i_{1}$ and $i_{2}$ be the indices of $s, s_{1}$ and $s, s_{2}$, and let $\mathbf{S}_{1}$ and $\mathbf{S}_{2}$ be their respective states. Let $\mathbf{S}_{1}^{\prime}$ and $\mathbf{S}_{2}^{\prime}$ be the respective states of $s, s_{1}^{\prime}$ and $s, s_{2}^{\prime}$. We restrict our choice to the following two options:

- index $s, s_{1}^{\prime}$ with $i_{1}$, and $s, s_{2}^{\prime}$ with $i_{2}$, or
- index $s, s_{1}^{\prime}$ with $i_{2}$, and $s, s_{2}^{\prime}$ with $i_{1}$.

We call such a choice a tracking choice. We say that a pair of segments in $S$ turns into a pair in $S^{\prime}$ when they have the same index. We denote $\mathbf{S} \rightarrow \mathbf{S}^{\prime}$ to specify that the pairs of segments with a given index go from the state $\mathbf{S}$ to the state $\mathbf{S}^{\prime}$. In the following, we use $\mathbf{S}_{1} \mathbf{S}_{2} \rightarrow \mathbf{S}_{1}^{\prime} \mathbf{S}_{2}^{\prime}$ as a shorthand notation to say that we have the two following tracking choices: either $\mathbf{S}_{1} \rightarrow \mathbf{S}_{1}^{\prime}$ and $\mathbf{S}_{2} \rightarrow \mathbf{S}_{2}^{\prime}$ or $\mathbf{S}_{1} \rightarrow \mathbf{S}_{2}^{\prime}$ and $\mathbf{S}_{2} \rightarrow \mathbf{S}_{1}^{\prime}$.

There are $3^{2}$ possible such transitions $\mathbf{S} \rightarrow \mathbf{S}^{\prime}$. Yet, the next two lemmas ensure that some transitions can be ruled out by tracking choices. Lemma 5.8.2 actually holds for any (possibly non-bipartite) matching, while Lemma 5.8.3 is specific to the red-on-a-line case. Both lemmas are proved analyzing the tracking choices of each possible position of a segment $s$ relatively to the flipping pair.

Lemma 5.8.2. There always exists a tracking choice avoiding the $\mathbf{H} \rightarrow \mathbf{X}$ transition.

Proof. There clearly exists a tracking choice avoiding the $\mathbf{H} \rightarrow \mathbf{X}$ transition unless we have either a transition (i) $\mathbf{H H} \rightarrow \mathbf{X S}$ or (ii) $\mathbf{H S} \rightarrow \mathbf{X X}$, where $\mathbf{S} \in\{\mathbf{X}, \mathbf{H}, \mathbf{T}\}$. We show that these two cases are not possible.
(i) $\mathbf{H H} \rightarrow \mathbf{X S}$ : If both the pairs $s, s_{1}$ and $s, s_{2}$ are $\mathbf{H}$ while at least one of the two pairs $s, s_{1}^{\prime}$ and $s, s_{2}^{\prime}$ is $\mathbf{X}$, then the final $\mathbf{X}$ state implies that $s$ crosses $s_{1}$ or $s_{2}$, which contradicts the two initial $\mathbf{H}$ states.
(ii) $\mathbf{H S} \rightarrow \mathbf{X X}$ : If one of the two pairs $s, s_{1}$ and $s, s_{2}$ is $\mathbf{H}$ while both pairs $s, s_{1}^{\prime}$ and $s, s_{2}^{\prime}$ are $\mathbf{X}$, then the two final $\mathbf{X}$ states imply that $s$ crosses $s_{1}^{\prime}$ and $s_{2}^{\prime}$. It follows that $s$ also crosses $s_{1}$ and $s_{2}$, which is again a contradiction.

State Tracking in the Red-on-a-Line Case. Figure 5.14 summarizes the notations for a generic red-on-a-line flip and an variable segment $s$. Figures 5.15, 5.16, 5.17, and 5.18 then provide "maps" of essentially all the possible situations of tracking choices in the red-on-a-line case. These figures are used to prove the next lemma.

Figure 5.14: Notations used in Figures 5.15, 5.16, 5.17, and 5.18 for a generic red-on-aline flip and an variable segment $s$.

Figure 5.15: The four possible cases for the position of $r$.
Figures 5.16, 5.17, and 5.18 are generated by a brute force computation of the states $\mathbf{S}_{1}, \mathbf{S}_{2}, \mathbf{S}_{1}^{\prime}, \mathbf{S}_{2}^{\prime}$ of the four pairs $s, s_{1}, s, s_{2}, s, s_{1}^{\prime}, s, s_{2}^{\prime}$ for each position case for $r$ (Figure 5.15) and for each position case for $b$ (in Figures 5.16, 5.17, and 5.18, each cell of the arrangement of lines corresponds to a position case for $b$ ). In the following, we make sure that no case is forgotten.

We assume, without loss of generality, that $r_{1}$ is on the left of $r_{2}$, and that $b_{1}$ is higher than $b_{2}$. Let $o$ be the intersection between the line $b_{1} b_{2}$ and the red-point line. There are, indeed, four possible open intervals for the position of $r$ on the red-point line: $]-\infty, o[] o,, r_{1}[,] r_{1}, r_{2}[$, and $] r_{2}, \infty[$ (Figure 5.15). This yields four cases, respectively. We do not explicitly describe case 4 as it is similar to case 2 . Indeed, case 2 and case 4 map to each other by exchanging the labels of $r_{1}$ and $r_{2}$, as well as $b_{1}$ and $b_{2}$. The fact

Figure 5.16: The case 1 "map" of all the possible red-on-a-line tracking choices. Tracking choices cannot avoid the transition $\mathbf{H} \rightarrow \mathbf{T}$ in the shaded region.

Figure 5.17: The case 2 "map" of all the possible red-on-a-line tracking choices. Tracking choices cannot avoid the transition $\mathbf{H} \rightarrow \mathbf{T}$ in the two shaded regions.

Figure 5.18: The case 3.1 "map" of all the possible red-on-a-line tracking choices.
that the point $o$ is still on the left of $r_{1}$ and $r_{2}$ is not a problem since we are studying incidence proprieties. Another way to see it, is to consider the projective plane.

As we have assumed the blue points to lie in the upper half-plane, these four cases branch into further sub-cases. However, no-loss-of-generality assumptions and symmetries simplify the analysis. Without loss of generality, we first assume that the lines $r_{1} b_{2}$ and $r_{2} b_{1}$ intersect in the upper half-plane, as it will only generate more cells to the upper part of the arrangement of lines.

Second, we examine case 3. Let $o_{1}$ be the intersection of the lines $r b_{2}$ and $r_{2} b_{1}$ (see Figure 5.18), and $o_{2}$ be the intersection of the lines $r b_{1}$ and $r_{1} b_{2}$. Case 3 decomposes into:

- case 3.1 where $o_{1}$ lies in the upper half-plane and $o_{2}$ in the lower,
- case 3.2 where both $o_{1}$ and $o_{2}$ lie in the upper half-plane,
- case 3.3 where $o_{1}$ lies in the lower half-plane and $o_{2}$ in the upper, and
- case 3.4 where both $o_{1}$ and $o_{2}$ lie in the lower half-plane.

Cases 3.1 and 3.3 are similar, while case 3.2 is just a superposition of both of them. More precisely, when compared to case 3.4, the extra cell of the arrangement generated by case 3.1 (the cell in the top left corner of Figure 5.18) corresponds to the possible tracking choices summarized by the notation XT $\rightarrow$ XT. Similarly, the extra cell generated by case 3.3 corresponds to $\mathbf{T X} \rightarrow \mathbf{T X}$. The two extra cells generated by case 3.2 are the same as the two previous ones. We thus assume case 3.1 (as it is easier to draw in our setting) without loss of generality. All these assumptions made, the remaining cases now correspond to Figures 5.16, 5.17, and 5.18.

The next lemma is similar to Lemma 5.8.2, but specific to red-on-a-line matchings. We will use it to additionally avoid the $\mathbf{H} \rightarrow \mathbf{T}$ transition. To state Lemma 5.8.3, we define the upper cone of two segments $r_{3} b_{3}, r_{4} b_{3}$ as the locus of the points that are separated from the horizontal line $r_{3} r_{4}$ by the two lines $r_{3} b_{3}$ and $r_{4} b_{3}$ (Figure 5.19(a)). We also define the upper ray of a segment as the open ray with the blue point as its origin, the segment as its direction, and going upwards (Figure 5.19(b)).

(a)

(b)

Figure 5.19: (a) The upper cone of $r_{3} b_{3}$ and $r_{4} b_{3}$ is shaded. (b) The upper ray of the segment is dotted and highlighted.

Lemma 5.8.3. In the Redonaline version, consider a set of three red-blue segments $\left\{s, s_{1}, s_{2}\right\}$, and the fip removing the pair of segments $s_{1}, s_{2}$ and inserting the pair of segments $s_{1}^{\prime}, s_{2}^{\prime}$.

If the blue endpoint $b$ of $s$ is not in any of the two upper cones of $s_{1}, s_{2}^{\prime}$ and $s_{2}, s_{1}^{\prime}$, then there always exists a tracking choice that avoids $\mathbf{H} \rightarrow \mathbf{T}$ for the pairs $s^{\text {s }} s_{1}$ and $s, s_{2}$ while still avoiding $\mathbf{H} \rightarrow \mathbf{X}$.

Proof. First, we check that there are only two possible upper cones defined by two segments of $s_{1}, s_{2}, s_{1}^{\prime}, s_{2}^{\prime}$. Indeed, only two pairs among them have a common blue point.

Then, we note that, for $s, s_{1}$ or $s, s_{2}$ to be in state $\mathbf{H}$, the red point $r$ of $s$ cannot be between $r_{1}$ and $r_{2}$, the red points of $s_{1}$ and $s_{2}$. Without loss of generality, we assume $r$ to lie on the left side of $r_{1}$ and $r_{2}$.

For $s, s_{1}^{\prime}$ or $s, s_{2}^{\prime}$ to be in state $\mathbf{T}, s$ has to cross at least one of the upper rays of $s_{1}^{\prime}$ or $s_{2}^{\prime}$.

The only two combinations of states for $\left\{s, s_{1}, s, s_{2}\right\}$ and $\left\{s, s_{1}^{\prime}, s, s_{2}^{\prime}\right\}$ which do not leave us the choice to avoid the $\mathbf{H} \rightarrow \mathbf{T}$ transition are $\{\mathbf{H}, \mathbf{T}\}$ and $\{\mathbf{T}, \mathbf{T}\}$, and $\{\mathbf{H}, \mathbf{X}\}$ and $\{\mathbf{T}, \mathbf{X}\}$. In any case, $b$ must be in the right most of the two upper cones of segments $s_{1}, s_{2}, s_{1}^{\prime}, s_{2}^{\prime}$. More precisely, $b$ lies in one of the three shaded regions of Figures 5.16 and 5.17. These three shaded regions also correspond to Figure 5.12 where case 1 is omitted but similar. The other cases are either not feasible geometrically, or with a possibility to make tracking choices so as to avoid transition $\mathbf{H} \rightarrow \mathbf{T}$.

Proof of Theorem 5.8.1. We are now ready to prove Theorem 5.8.1.
Proof. Let $f(S)$ be the total number of flips performed by the algorithm on an $n$-segment input matching $S$ and let $g(S)$ be the number of flips performed by the algorithm before the recursive calls. Let $S_{\text {rec }}$ denote the matching before the recursive calls. The recursive calls take two submatchings of $S_{\text {rec }}$ that we call $S_{1}$ and $S_{2}$, yielding the following recurrence relation.

$$
f(S)=f\left(S_{1}\right)+f\left(S_{2}\right)+g(S)
$$

Let $\bar{h}(S)$ be the number of $\mathbf{X}$-pairs plus the number of $\mathbf{T}$-pairs in a matching $S$, that is, the number of pairs that are not $\mathbf{H}$-pairs. Lemma 5.8.3 ensures that

$$
g(S) \leq \bar{h}(S)-\bar{h}\left(S_{\mathrm{rec}}\right) \leq \bar{h}(S)-\bar{h}\left(S_{1}\right)-\bar{h}\left(S_{2}\right)
$$

Clearly, $f(\emptyset)=0$. We suppose that, for all $S^{\prime}$ with less than $n$ segments, we have $f\left(S^{\prime}\right) \leq \bar{h}\left(S^{\prime}\right)$. Then by induction we get

$$
f(S) \leq \bar{h}\left(S_{1}\right)+\bar{h}\left(S_{2}\right)+\bar{h}(S)-\bar{h}\left(S_{1}\right)-\bar{h}\left(S_{2}\right)=\bar{h}(S)
$$

Theorem 5.8.1 follows since $\bar{h}(S) \leq\binom{ n}{2}$.
State Tracking in the Convex Case. State tracking also applies to the widely studied convex case, providing a more conceptual proof of Theorem 3.2.2 [17].

Alternative proof of Theorem 3.2.2 [17]. In the convex case, the T-state does not exist. Lemma 5.8.2 thus ensures that the number of $\mathbf{H}$-pairs increases by at least 1 at each flip.

## Chapter 6

## Untangling with Insertion Choice

In this chapter, we devise strategies for insertion choice to untangle multisets of segments, therefore providing upper bounds on several versions of $\mathbf{d}^{\mathrm{I}}$. Recall that such insertion strategies do not choose which pair of crossing segments is removed, but only which pair of segments with the same endpoints is subsequently inserted. We start with a tight bound in Convex version (where the point set is in convex position), followed by the Separated version (where the point set $P=C \cup T$ has some points $C$ in convex position and the other points $T$ outside the convex hull of $C$ and separated from $C$ by two parallel lines).

### 6.1 Upper Bound for Convex Position

Let $P=C=\left\{p_{1}, \ldots, p_{|C|}\right\}$ be a set of points in convex position sorted in counterclockwise order along the convex hull boundary (Figure 6.1(a)). Given a segment $p_{a} p_{b}$, we define the depth $\delta\left(p_{a} p_{b}\right)=|b-a| .{ }^{1}$ We use the depth to prove the following theorem.

Figure 6.1: (a) A multigraph $(C, S)$ with $|C|=14$ points in convex position and $n=9$ segments. (b) Insertion choice for Case 1 and 2 of the proof of Theorem 6.1.1. (c) Insertion choice for Case 3.

Theorem 6.1.1 ([31]). Consider a multiset $S$ of $n$ segments with endpoints $P=C$ in convex position.

In the Convex Multigraph version, there exists an insertion strategy such that for any removal strategy, the resulting untangle sequence of $S$ is of length $O(n \log |C|)=$ $O(n \log n)$.

[^17]In other words, we have the following upper bound:

$$
\mathbf{d}_{\text {Convex Multigraph }}^{\mathrm{I}}(n)=O(n \log |P|)=O(n \log n) .
$$

Proof. Let the potential function

$$
\varpi(S)=\prod_{s \in S} \delta(s) .
$$

As $\delta(s) \in\{1, \ldots,|C|-1\}$, we have that $\varpi(S)$ is integer, positive, and at most $|C|^{n}$. Next, we show that for any flipped pair of segments $p_{a} p_{b}, p_{c} p_{d}$ there exists an insertion choice that multiplies $\varpi(S)$ by a factor of at most $3 / 4$, and the theorem follows.

Consider a flip of a segment $p_{a} p_{b}$ with a segment $p_{c} p_{d}$ and assume without loss of generality that $a<c<b<d$. The contribution of the pair of segments $p_{a} p_{b}, p_{c} p_{d}$ to the potential $\varpi(S)$ is the factor $f=\delta\left(p_{a} p_{b}\right) \delta\left(p_{c} p_{d}\right)$. Let $f^{\prime}$ be the factor corresponding to the pair of inserted segments.

Case 1: If $\delta\left(p_{a} p_{c}\right) \leq \delta\left(p_{c} p_{b}\right)$, then we insert the segments $p_{a} p_{c}$ and $p_{b} p_{d}$ and we get $f^{\prime}=\delta\left(p_{a} p_{c}\right) \delta\left(p_{b} p_{d}\right)$ (Figure 6.1(b)). We notice $\delta\left(p_{a} p_{b}\right)=\delta\left(p_{a} p_{c}\right)+\delta\left(p_{c} p_{b}\right)$. It follows $\delta\left(p_{a} p_{c}\right) \leq \delta\left(p_{a} p_{b}\right) / 2$ and we have $\delta\left(p_{b} p_{d}\right) \leq \delta\left(p_{c} p_{d}\right)$ and then $f^{\prime} \leq f / 2$.

Case 2: If $\delta\left(p_{b} p_{d}\right) \leq \delta\left(p_{c} p_{b}\right)$, then we insert the same segments $p_{a} p_{c}$ and $p_{b} p_{d}$ as previously. We have $\delta\left(p_{a} p_{c}\right) \leq \delta\left(p_{a} p_{b}\right)$ and $\delta\left(p_{b} p_{d}\right) \leq \delta\left(p_{c} p_{d}\right) / 2$, which gives $f^{\prime} \leq f / 2$.

Case 3: If (i) $\delta\left(p_{a} p_{c}\right)>\delta\left(p_{c} p_{b}\right)$ and (ii) $\delta\left(p_{b} p_{d}\right)>\delta\left(p_{c} p_{b}\right)$, then we insert the segments $p_{a} p_{d}$ and $p_{c} p_{b}$ (Figure 6.1(c)). The contribution of the new pair of segments is $f^{\prime}=\delta\left(p_{a} p_{d}\right) \delta\left(p_{c} p_{b}\right)$. We introduce the coefficients $x=\frac{\delta\left(p_{a} p_{c}\right)}{\delta\left(p_{c} p_{b}\right)}$ and $y=\frac{\delta\left(p_{b} p_{d}\right)}{\delta\left(p_{c} p_{b}\right)}$ so that $\delta\left(p_{a} p_{c}\right)=x \delta\left(p_{c} p_{b}\right)$ and $\delta\left(p_{b} p_{d}\right)=y \delta\left(p_{c} p_{b}\right)$. It follows that $\delta\left(p_{a} p_{b}\right)=(1+x) \delta\left(p_{c} p_{b}\right)$, $\delta\left(p_{c} p_{d}\right)=(1+y) \delta\left(p_{c} p_{b}\right)$ and $\delta\left(p_{a} p_{d}\right)=(1+x+y) \delta\left(p_{c} p_{b}\right)$. The ratio $f^{\prime} / f$ is equal to a function $g(x, y)=\frac{1+x+y}{(1+x)(1+y)}$. Due to (i) and (ii), we have that $x \geq 1$ and $y \geq 1$. In other words, we can upper bound the ratio $f^{\prime} / f$ by the maximum of the function $g(x, y)$ with $x, y \geq 1$. It is easy to show that the function $g(x, y)$ is decreasing with both $x$ and $y$. Then its maximum is obtained for $x=y=1$ and it is equal to $3 / 4$, showing that $f^{\prime} \leq 3 f / 4$.

### 6.2 Upper Bound for Points Separated by Two Parallel Lines

In this section, we prove the following theorem, which is a generalization of Theorem 6.1.1. We extend our standard general position assumptions to also exclude pairs of endpoints with the same $y$-coordinate.

Theorem 6.2.1 ([31]). Consider a multiset $S$ of $n$ segments with endpoints $P$ partitioned into $P=C \cup T_{1} \cup T_{2}$ where $C$ is in convex position and there exist two horizontal lines $\ell_{1}, \ell_{2}$, with $T_{1}$ above $\ell_{1}$ above $C$ above $\ell_{2}$ above $T_{2}$. We define the parameter $t$ as the sum of the degrees of the points in $T=T_{1} \cup T_{2}$.

In the Separated Multigraph version, there exists an insertion strategy such that for any removal strategy, the resulting untangle sequence of $S$ is of length $O(t|P| \log |C|+$ $n \log |C|)=O(t n \log n)$.

Figure 6.2: (a) Statement of Theorem 6.2.1. (b) Some insertion choices in the proof of Theorem 6.2.1.

In other words, we have the following upper bound:

$$
\mathbf{d}_{\text {Separated Multigraph }}^{\mathrm{I}}(n, t)=O(t|P| \log |C|+n \log |C|)=O(t n \log n) .
$$

Proof. We start by describing the insertion choice for flips involving at least one point in $T$. Let $p_{1}, \ldots, p_{|P|}$ be the points $P$ sorted vertically from top to bottom. Consider a flip involving the points $p_{a}, p_{b}, p_{c}, p_{d}$ with $a<b<c<d$. The insertion choice is to create the segments $p_{a} p_{b}$ and $p_{c} p_{d}$. See Figure 6.2(b). As in the proof of Theorem 3.1.4 [19], we define the potential $\eta$ of a segment $p_{i} p_{j}$ as

$$
\eta\left(p_{i} p_{j}\right)=|i-j|
$$

Notice that $\eta$ is an integer between 1 and $|P|-1$. We define $\eta_{T}(S)$ as the sum of $\eta\left(p_{i} p_{j}\right)$ for $p_{i} p_{j} \in S$ with $p_{i}$ or $p_{j}$ in $T$. Notice that $0<\eta_{T}(S)<t|P|$. It is easy to verify that any flip involving a point in $T$ decreases $\eta_{T}(S)$ and other flips do not change $\eta_{T}(S)$. Hence, the number of flips involving at least one point in $T$ is $O(t|P|)$.

For the flips involving only points of $C$, we use the same choice as in the proof of Theorem 6.1.1. The potential function

$$
\varpi(S)=\prod_{p_{i} p_{j} \in S:}: p_{i} \in C \text { and } p_{j} \in C \text { } \delta\left(p_{i} p_{j}\right)
$$

is at most $|C|^{n}$ and decreases by a factor of at most $3 / 4$ at every flip that involves only points of $C$.

However, $\varpi(S)$ may increase by a factor of $O\left(|C|^{2}\right)$ when performing a flip that involves a point in $T$. As such flips only happen $O(t|P|)$ times, the total increase is at most a factor of $|C|^{O(t|P|)}$.

Concluding, the number of flips involving only points in $C$ is at most

$$
\log _{4 / 3}\left(|C|^{O(n)}|C|^{O(t|P|)}\right)=O(n \log |C|+t|P| \log |C|) .
$$

## Chapter 7

## Untangling with Both Choices

In this chapter, we devise strategies for insertion and removal choices to untangle a multiset of segments, therefore providing upper bounds on several versions of $\mathbf{d}_{\text {A11 out }}^{\mathrm{RI}}$. Recall that such strategies choose which pair of crossing segments is removed and which pair of segments with the same endpoints is subsequently inserted.

Throughout this chapter, we work in the Allout version, i.e., with the following assumptions. We assume that the point set $P$ is partitioned into $P=C \cup T$ where $C$ is in convex position, and we define the parameter $t$ as the sum of the degrees of the points in $T$. We additionally assume that the points of $T$ lie outside the convex hull of $C$.

We start with the case where $T$ is separated by two parallel lines from $C$. Afterwards, we prove an important lemma and apply it to untangle a matching.

### 7.1 Upper Bound for Points Separated by Two Parallel Lines

In this section, we prove an upper bound on $\mathbf{d}_{\text {Separated Multigraph }}^{\mathrm{RI}}$. Recall that, in the Separated version, $T$ is separated from $C$ by two parallel lines. In this version, our bound of $O(n+t|P|)$ interpolates the tight convex bound of $O(n)$ from Theorem 3.2.13 [17, 31] and the $O(t|P|)$ bound from Theorem 3.1.4 [19] for $t$ arbitrary segments. We extend our standard general position assumptions to also exclude pairs of endpoints with the same $y$-coordinate.

Theorem 7.1.1 ([31]). Consider a multiset $S$ of $n$ segments with endpoints $P$ partitioned into $P=C \cup T_{1} \cup T_{2}$ where $C$ is in convex position and there exist two horizontal lines $\ell_{1}, \ell_{2}$, with $T_{1}$ above $\ell_{1}$ above $C$ above $\ell_{2}$ above $T_{2}$. We define the parameter $t$ as the sum of the degrees of the points in $T=T_{1} \cup T_{2}$.

In the Separated Multigraph version, there exists an untangle sequence of $S$ of length $O(n+t|P|)=O(t n)$.

In other words, we have the following upper bound:

$$
\mathbf{d}_{\text {Separated Multigraph }}^{\mathrm{RI}}(n, t)=O(n+t|P|)=O(t n)
$$

Proof. The algorithm runs in two phases.

Phase 1. We use removal choice to perform the flips involving a point in $T$. At the end of the first phase, there can only be crossings among segments with all endpoints in $C$. The insertion choice for the first phase is the following. Let $p_{1}, \ldots, p_{|P|}$ be the points $P$ sorted vertically from top to bottom. Consider a flip involving the points $p_{a}, p_{b}, p_{c}, p_{d}$ with $a<b<c<d$. The insertion choice is to create the segments $p_{a} p_{b}$ and $p_{c} p_{d}$. As in the proofs of Theorem 6.1.1 [31] and of Theorem 6.2.1 [31], we define the potential $\delta$ of a segment $p_{i} p_{j}$ as $\delta\left(p_{i} p_{j}\right)=|i-j| .{ }^{1}$ Notice that $\delta$ is an integer from 1 to $|P|-1$. We define $\delta(S)$ as the sum of $\delta\left(p_{i} p_{j}\right)$ for $p_{i} p_{j} \in S$ with $p_{i}$ or $p_{j}$ in $T$. Notice that $0<\delta(S)<t|P|$. It is easy to verify that any flip involving a point in $T$ decreases $\delta(S)$. Hence, the number of flips in Phase 1 is $O(t|P|)$.

Phase 2. Since $T$ is outside the convex hull of $C$, flips between segments with all endpoints in $C$ cannot create crossings with the other segments, which are guaranteed to be crossing free at this point. Hence, it suffices to run an algorithm to untangle a convex set with removal and insertion choice from Theorem 3.2.13, which performs $O(n)$ flips.

### 7.2 Upper Bound for Matchings with Points Outside a Convex

In this section, we prove an upper bound on $\mathbf{d}_{\text {A11 out Matching. }}^{\mathrm{RI}}$. This upper bound may not hold for the Multigraph version as the proof uses a lemma specific the Matching version.

## Liberating a Line

In this section, we prove the following key lemma, which we use in the following section. The lemma only applies to matchings and it is easy to find a counter-example for multisets ( $S$ consisting of $n$ copies of a single segment that crosses $p q$ ).

Lemma 7.2.1. Consider a set $S$ of $n$ segments with endpoints $C$ in convex position and a segment qq' intersecting the interior of the convex hull of $C$ such that $\left(C \cup\left\{q, q^{\prime}\right\}, S \cup\right.$ \{qq'\}) forms a matching.

There exists a flip sequence starting at $S \cup\left\{q q^{\prime}\right\}$ of length $O(n)$ which ends with a set of segments that do not cross the line $q q^{\prime}$ (the line $q q^{\prime}$ splits the final set of segments).

Proof. For each flip performed in the subroutine described hereafter, at least one of the inserted segments does not cross the line $q q^{\prime}$ and is removed from $S$ (see Figure 7.1).

Preprocessing. First, we remove from $S$ the segments that do not intersect the line $q q^{\prime}$, as they are irrelevant. Second, anytime two segments in $S$ cross, we flip them choosing to insert the pair of segments not crossing the line $q q^{\prime}$. One such flip removes two segments from $S$. Let $p_{1} p_{2}$ (respectively $p_{2 n-1} p_{2 n}$ ) be the segment in $S$ whose intersection point with $q q^{\prime}$ is the closest from $q$ (respectively $q^{\prime}$ ). Without loss of generality, assume that the points $p_{1}$ and $p_{2 n-1}$ are on the same side of the line $q q^{\prime}$.

[^18]

Figure 7.1: An untangle sequence of the subroutine to liberate the line $q q^{\prime}$ (with $n=4$ ).

First flip. Lemma 7.2.2 applied to the segment $q q^{\prime}$ and the triangle $p_{1} p_{2} p_{2 n-1}$ shows that at least one of the segments among $q p_{2 n-1}, q^{\prime} p_{1}, q^{\prime} p_{2}$ intersects all the segments of $S$. Without loss of generality, assume that $q p_{2 n-1}$ is such a segment, i.e., that $q p_{2 n-1}$ crosses all segments of $S \backslash\left\{p_{2 n-1} p_{2 n}\right\}$. We choose to remove the segments $q q^{\prime}$ and $p_{2 n-1} p_{2 n}$, and we choose to insert the segments $q p_{2 n-1}$ and $q^{\prime} p_{2 n}$. As the segment $q^{\prime} p_{2 n}$ does not cross the line $q q^{\prime}$, we remove it from $S$.

Second flip. We choose to flip the segments $q p_{2 n-1}$ and $p_{1} p_{2}$. If $n$ is odd, we choose to insert the pair of segments $q p_{1}, p_{2} p_{2 n-1}$. If $n$ is even, we insert the segments $q p_{2}, p_{1} p_{2 n-1}$.

By convexity, one of the inserted segment (the one with endpoints in $C$ ) crosses all other $n-2$ segments. The other inserted segment (the one with $q$ as one of its endpoints) does not cross the line $q q^{\prime}$, so we remove it from $S$. Note that the condition on the parity of $n$ is there only to ensure that the last segment $p_{2 n-3} p_{2 n-2}$ is dealt with at the last flip.

Remaining flips. We describe the third flip. The remaining flips are performed similarly. Let $s$ be the previously inserted segment. Let $p_{3} p_{4}$ be the segment in $S$ whose intersection point with $q q^{\prime}$ is the closest from $q$. Without loss of generality, assume that $p_{3}$ is on the same side of the line $q q^{\prime}$ as $p_{1}$ and $p_{2 n-1}$.

We choose to flip $s$ with $p_{3} p_{4}$. If $s=p_{2} p_{2 n-1}$, we choose to insert the pair of segments $p_{2} p_{4}, p_{3} p_{2 n-1}$. If $s=p_{1} p_{2 n-1}$, we choose to insert the pair of segments $p_{1} p_{3}, p_{4} p_{2 n-1}$.

By convexity, one inserted segment (the one with $p_{2 n-1}$ as an endpoint) crosses all other $n-3$ segments. The other inserted segment does not cross the line $q q^{\prime}$, so we remove it from $S$. Note that the insertion choice described is the only viable one, as the alternative would insert a crossing-free segment crossing the line $q q^{\prime}$ that cannot be removed.

Auxiliary Lemma of Section 7.2. In this section, we prove Lemma 7.2.2 used in the proof of Lemma 7.2.1.

Recall that, in the proof of Lemma 7.2.1, we have a convex quadrilateral $p_{1} p_{2} p_{2 n} p_{2 n-1}$ and a segment $q q^{\prime}$ crossing the segments $p_{1} p_{2}$ and $p_{2 n} p_{2 n-1}$ in this order when drawn from $q$ to $q^{\prime}$, and we invoke Lemma 7.2.2 to show that at least one of the segments among $q p_{2 n-1}, q^{\prime} p_{1}, q^{\prime} p_{2}$ intersects all the segments of $S$. Before proving Lemma 7.2.2, we detail how to apply it to this context.

Lemma 7.2.2 applied to the segment $q q^{\prime}$ and the triangle $p_{1} p_{2} p_{2 n-1}$ asserts that at least one of the following pairs of segments cross: $q p_{2 n-1}, p_{1} p_{2}$, or $q^{\prime} p_{1}, p_{2} p_{2 n-1}$, or
$q^{\prime} p_{2}, p_{1} p_{2 n-1}$. If the segments $q p_{2 n-1}, p_{1} p_{2}$ cross, then we are done. If the segments $q^{\prime} p_{1}, p_{2} p_{2 n-1}$ cross, then the segments $q^{\prime} p_{1}, p_{2 n} p_{2 n-1}$ also cross and we are done. If the segments $q^{\prime} p_{2}, p_{1} p_{2 n-1}$ cross, then the segments $q^{\prime} p_{2}, p_{2 n} p_{2 n-1}$ also cross and we are done.

Next, we state and prove Lemma 7.2.2.
Lemma 7.2.2. For any triangle $p_{1} p_{2} p_{3}$, for any segment $q q^{\prime}$ intersecting the interior of the triangle $p_{1} p_{2} p_{3}$, there exists a segment $s \in\left\{q p_{1}, q p_{2}, q p_{3}, q^{\prime} p_{1}, q^{\prime} p_{2}, q^{\prime} p_{3}\right\}$ that intersects the interior of the triangle $p_{1} p_{2} p_{3}$.

Proof. If all $p_{1}, p_{2}, p_{3}, q, q^{\prime}$ are in convex position, then $q$ and the point among $p_{1}, p_{2}, p_{3}$ that is not adjacent to $q$ on the convex hull boundary define the segment $s$. Otherwise, since $q, q^{\prime}$ are not adjacent on the convex hull boundary, assume without loss of generality that $p_{1}$ is not a convex hull vertex and $q, p_{2}, q^{\prime}, p_{3}$ are the convex hull vertices in order. Then, either the segment $p_{1} q$ or the segment $p_{1} q^{\prime}$ intersects the segment $p_{2} p_{3}$.

## Proof of the Upper Bound

We are now ready to prove the following theorem, which only applies to matchings because it uses Lemma 7.2.1.

Theorem 7.2.3 ([31]). Consider a set $S$ of $n$ segments with endpoints $P$ partitioned into $P=C \cup T$ where $C$ is in convex position and $T$ is outside the convex hull of $C$, and such that $(P, S)$ forms a matching. We define the parameter $t$ as the sum of the degrees of the points in $T$.

In the Allout Matching version, there exists an untangle sequence of length $O\left(t^{3} n\right)$. In other words, we have the following upper bound:

$$
\mathbf{d}_{\text {A11out Matching }}^{\mathrm{RI}}(n, t)=O\left(t^{3} n\right)
$$

Proof. Throughout this proof, we partition the $T T$-segments into two types: $T T_{\text {in }}{ }^{-}$ segment if it intersects the interior of the convex hull of $C$ and $T T_{\text {out-segment }}$ otherwise. As in the proof of Theorem 3.1.3, we define the potential $\Lambda_{\ell}(S)$ of a line $\ell$ as the number of segments of $S$ crossing $\ell$.
$T T$-segments. At any time during the untangle procedure, if there is a $T T_{\mathrm{in}}$-segment $s$ that crosses more than $t$ segments, we apply Lemma 7.2.1 to liberate $s$ from every $C C$-segment using $O(n)$ flips. Let $\ell$ be the line containing $s$. Since $\Lambda_{\ell}$ cannot increase (Lemma 3.1.1), $\Lambda_{\ell}<t$ after Lemma 7.2.1, and there are $O\left(t^{2}\right)$ different $T T_{\mathrm{in}}$-segments in $S$, it follows that Lemma 7.2.1 is applied $O\left(t^{2}\right)$ times, performing a total $O\left(t^{2} n\right)$ flips. As the number of times $s$ is inserted and removed differ by at most 1 and $\Lambda_{\ell}$ decreases at each flip that removes $s$, it follows that $s$ participates in $O(t)$ flips. As there are $O\left(t^{2}\right)$ different $T T_{\mathrm{in}}$-segments in $S$, the total number of flips involving $T T_{\mathrm{in}}$-segments is $O\left(t^{3}\right)$.

We define a set $L$ of $O(t)$ lines as follows. For each point $q \in T$, we have two lines $\ell_{1}, \ell_{2} \in L$ that are the two tangents of the convex hull of $C$ that pass through $q$. As the lines $\ell \in L$ do not intersect the interior of the convex hull of $C$, the potential $\Lambda_{\ell}=O(t)$. When flipping a $T T_{\text {out-segment }} q_{1} q_{2}$ with another segment $q_{3} p$ with $q_{3} \in T$ ( $p$ may be in $T$ or in $C$ ), we make the insertion choice of creating a $T T_{\text {out }}$-segment $q_{1} q_{3}$ such
that there exists a line $\ell \in L$ whose potential $\Lambda_{\ell}$ decreases. It is easy to verify that $\ell$ always exist (see Lemma 7.2.4 and Lemma 7.2.5). Hence, the number of flips involving $T T_{\text {out }}$-segments is $O\left(t^{2}\right)$ and the number of flips involving $T T$-segments in general is $O\left(t^{3}\right)$.

All except pairs of $C C$-segments. We keep flipping segments that are not both $C C$-segments with the following insertion choices. Whenever we flip two $C T$-segments, we make the insertion choice of creating a $T T$-segment. Hence, as the number of flips involving $T T$-segments is $O\left(t^{3}\right)$, so is the number of flips of two $C T$-segments.

Whenever we flip a $C T$-segment $p_{1} q$ with $q \in T$ and a $C C$-segment $p_{3} p_{4}$, we make the following insertion choice. Let $v(q)$ be a vector such that the dot product $v(q) \cdot q<v(q) \cdot p$ for all $p \in C$, that is, $v$ is orthogonal to a line $\ell$ separating $q$ from $C$ and $v$ is pointing towards $C$. We define the potential $\rho\left(p_{i} q\right)$ of a segment with $p_{i} \in C$ and $q \in T$ as the number of points $p \in C$ such that $v(q) \cdot p<v(q) \cdot p_{i}$, that is the number of points in $C$ before $p_{i}$ in direction $v$. We choose to insert the segment $p_{i} q$ that minimizes $\rho\left(p_{i} q\right)$ for $i \in\{3,4\}$. Let $\rho(S)$ be the sum of $\rho\left(p_{i} q\right)$ for all $C T$-segments $p_{i} q$ in $S$. It is easy to see that $\rho(S)$ is $O(t|C|)$ and decreases at each flip involving a $C T$-segment (not counting the flips inside Lemma 7.2.1).

There are two situation in which $\rho(S)$ may increase. One is when Lemma 7.2.1 is applied, which happens $O\left(t^{2}\right)$ times. Another one is when a $T T$-segment and a $C C$-segment flip, creating two $C T$-segments, which happens $O\left(t^{3}\right)$ times. At each of these two situations, $\rho(S)$ increases by $O(|C|)$. Consequently, the number of flips between a $C T$-segment and a $C C$-segment is $O\left(t^{3}|C|\right)=O\left(t^{3} n\right)$.
$C C$-segments. By removal choice, we choose to flip the pairs of $C C$-segments last (except for the ones flipped in Lemma 7.2.1). As $T$ is outside the convex hull of $C$, flipping two $C C$-segments does not create crossings with other segments (by the splitting lemma, i.e., Lemma 2.6.1 [19, 31]). Hence, we apply Theorem 3.2.13 to untangle the remaining segments using $O(n)$ flips.

Auxiliary Lemmas of Section 7.2 In this section, we prove Lemma 7.2.5 and Lemma 7.2.4 used in the proof of Theorem 7.2.3.

Recall that, in the proof of Theorem 7.2.3, we define a set $L$ of lines as follows. For each point $q \in T$, we have two lines $\ell_{1}, \ell_{2} \in L$ that are the two tangents of the convex hull of $C$ that pass through $q$. When flipping a $T T_{\text {out }}$-segment $q_{1} q_{2}$ with another segment $q_{3} p$ with $q_{3} \in T$ ( $p$ may be in $T$ or in $C$ ), we make the insertion choice of creating a $T T_{\text {out-segment }} q_{1} q_{3}$ such that there exists a line $\ell \in L$ whose potential $\Lambda_{\ell}$ decreases. We invoke Lemma 7.2.4 and Lemma 7.2.5 to show that such a line $\ell$ always exist.

Indeed, by Lemma 7.2.4, it is enough to show that there exists a line $\ell \in L$ containing one of the points $q_{1}, q_{2}, q_{3}$ that crosses one of the segments $q_{1} q_{2}$ or $q_{3} p$. This is precisely what Lemma 7.2.5 shows.

Next, we state prove Lemma 7.2.4 and Lemma 7.2.5.
Lemma 7.2.4. Consider two crossing segments $p_{1} p_{2}, p_{3} p_{4}$ and a line $\ell$ containing $p_{1}$ and crossing $p_{3} p_{4}$. Then, one of the two pairs of segments $p_{1} p_{3}, p_{2} p_{4}$ or $p_{1} p_{4}, p_{2} p_{3}$ does
not cross $\ell$. In other words, there exists an insertion choice for a flip removing $p_{1} p_{2}, p_{3} p_{4}$ such that the number of segments crossing $\ell$ decreases.

Proof. Straightforward.
Lemma 7.2.5. Consider a closed convex body $B$ and two crossing segments $q_{1} q_{3}, q_{2} q_{4}$ whose endpoints $q_{1}, q_{2}, q_{3}$ are not in $B$, and whose endpoint $q_{4}$ is not in the interior of $B$. If the segment $q_{1} q_{3}$ does not intersect the interior of $B$, then at least one of the six lines tangent to $B$ and containing one of the endpoints $q_{1}, q_{2}, q_{3}$ is crossing one of the segments $q_{1} q_{3}, q_{2} q_{4}$ (Figure 7.2(a)). (General position is assumed, meaning that the aforementioned six lines are distinct, i.e., each line does not contain two of the points $q_{1}, q_{2}, q_{3}, q_{4}$.)

(a)

(b)

Figure 7.2: (a) In the statement of Lemma 7.2.5, we assert the existence of points, circled in the figure, which are the intersection of a line tangent to $B$ and containing one of the points $q_{1}, q_{2}, q_{3}$. (b) In the proof of Lemma 7.2 .5 by contraposition, we exhibit a point, circled in the figure, showing that $B$ intersects one of the segment $q_{1} q_{3}$.

Proof. For all $i \in\{1,2,3\}$, let $\ell_{i}$ and $\ell_{i}^{\prime}$ be the two lines containing $q_{i}$ and tangent to $B$ (Figure 7.2(b)). By contraposition, we assume that none of the six lines $\ell_{1}, \ell_{1}^{\prime}, \ell_{2}, \ell_{2}^{\prime}, \ell_{3}, \ell_{3}^{\prime}$ crosses one of the segments $q_{1} q_{3}, q_{2} q_{4}$. In other words, we assume that the six lines are tangent to the convex quadrilateral $q_{1} q_{2} q_{3} q_{4}$. It is well known that, if $m \geq 5$, then any arrangement of $m$ lines or more admits at most one face with $m$ edges (see [49] for example). Therefore, $B$ is contained in the same face of the arrangement of the six lines as the quadrilateral $q_{1} q_{2} q_{3} q_{4}$. Let $o_{1}$ (respectively $o_{1}^{\prime}$ ) be a contact point between the line $\ell_{1}$ (respectively $\ell_{1}^{\prime}$ ) and the convex body $B$. The segment $o_{1} o_{1}^{\prime}$ crosses the segment $q_{1} q_{3}$ and is contained in $B$ by convexity (Figure 7.2(b)), concluding the proof by contraposition.

## Chapter 8

## Intractability of the Shortest Bipartite Untangle Sequence

This chapter is dedicated to the proof of the intractability of the shortest untangle sequence in the Bipartite Matching version (and of any constant factor approximation of it). Specifically, we prove the $\mathcal{N} \mathcal{P}$-hardness of the following problem. Let $d(S)$ denote the length of the shortest untangle sequences of $S$.

Problem 1. Let $\alpha \geq 1$ be a constant.
Input: S, a set of segments with rational coordinates forming a bipartite matching. Output: An untangle sequence starting at $S$ of length at most $\alpha$ times $d(S)$.

We have the following theorem.
Theorem 8.0.1. Problem 1 is $\mathcal{N} \mathcal{P}$-hard for all $\alpha \geq 1$.

### 8.1 Reduction Strategy

De Berg and Khosravi [37] showed that the rectilinear planar monotone 3-SAT problem ( RPM 3-SAT) is $\mathcal{N} \mathcal{P}$-hard. The RPM 3-SAT problem is a special case of the classic 3-SAT problem in which the clauses consist only of either all positive or all negative literals and the layout is planar (Figure 8.1). We reduce RPM 3-SAT to Problem 1. The key elements of the reduction are described next.

Given a planar embedding of an RPM 3-CNF formula $\varphi$ (Figure 8.1), we construct a matching $S_{\varphi}$ of polynomial size. The property of this matching $S_{\varphi}$ is that its shortest untangle sequence has a length below a certain constant if $\varphi$ is satisfiable and above $\alpha$ times this constant otherwise. Figure 8.2 shows the matching $S_{\varphi}$ corresponding to the formula $\varphi=\left(x_{1} \vee x_{2} \vee x_{3}\right) \wedge\left(x_{3} \vee x_{4} \vee x_{5}\right) \wedge\left(x_{3} \vee x_{5} \vee x_{6}\right) \wedge\left(\overline{x_{2}} \vee \overline{x_{3}} \vee \overline{x_{4}}\right)$ from Figure 8.1.

The aforesaid matching $S_{\varphi}$ is built using two types of gadgets. The variable rectangles are replaced by variable gadgets (Figure 8.3). The clause rectangles together with the corresponding edges are replaced with padded clause gadgets. A padded clause gadget is represented in Figure 8.7 with plain segments. Throughout all the figures in this section, the dashed segments represent all the possibly created segments after any sequence of flips.

A variable gadget is a three-segment matching with two crossings. It allows for two possible flips, either of which produces a crossing-free matching, as shown in Figure 8.3. The flip generating the topmost segment stands for false ( $x=0$ in Figure 8.3), while the flip generating the bottom segment stands for true $(x=1)$.

A clause gadget is an OR gate with three inputs (Figure 8.8). The RPM 3-CNF clauses are either positive or negative. We describe the gadget for a positive clause, but the gadget for a negative clause can be defined analogously (by a vertical reflection). Three variable gadgets are the inputs of a clause gadget. In the crossing-free matching obtained for the clause gadget, the presence of the topmost segment $\left(r_{4} b_{7}\right.$ in Figures 8.5, 8.6, 8.7, and 8.8) stands for a false output.

A padding gadget is a gadget that serves to force an arbitrarily large number $k$ of flips if a clause is false. It consists of a series of $k$ non-crossing segments (the plain segments in Figure 8.6, $r_{4} b_{7}$ aside). A padded clause gadget is a clause gadget coupled with a padding gadget in such a way that the presence of the output segment triggers $k$ extra flips (Figure 8.7).

Let $c$ be the number of clauses and $v$ be the number of variables of the formula $\varphi$. If $\varphi$ is satisfiable, then the shortest untangle sequence of $S_{\varphi}$ has at most 5 flips per clause plus 1 flip per variable. In this case, we have $d\left(S_{\varphi}\right) \leq 5 c+v$. We choose the size of the padding gadget so that a non-satisfied clause triggers $k=\alpha(5 c+v)+1$ flips. If the formula $\varphi$ is not satisfiable, then at least one of the padding gadgets is triggered and $d\left(S_{\varphi}\right)>\alpha(5 c+v)$.

### 8.2 The Problem to Be Reduced

In RPM 3-SAT, the graph of a conjunctive normal form (CNF) formula is the bipartite graph with the variables and clauses as vertices, and where there is an edge between a variable and a clause if and only if the clause contains the variable. A clause is said to be positive if it contains only positive variables; it is said to be negative if it contains only negative variables. A CNF formula is monotone if each clause is either positive or negative.

A rectilinear planar monotone 3 -CNF ( $R$ PM 3-CNF) formula is a monotone formula with 3 -variables per clause whose graph can be drawn with the following conventions (Figure 8.1). (i) The variables and the clauses are represented by axis-parallel nonoverlapping closed rectangles. (ii) The variable rectangle centroids lie on the $x$-axis. (iii) The positive clause rectangles are above the $x$-axis, the negative ones, below. (iv) The edges connecting a variable to a clause are vertical line segments and do not cross any other rectangle. We call such a drawing a planar embedding of $\varphi$.

### 8.3 Variable Gadgets

A variable gadget is a three-segment matching built on the four endpoints of an axisparallel rectangle as follows (Figure 8.3). The two leftmost endpoints of the rectangle are colored red, the two rightmost ones are colored blue. One of the segments of the matching is the diagonal joining the bottom left red point to the top right blue point. We add one red point on the vertical line cutting the rectangle in two symmetric halves,

Figure 8.1: A planar embedding of an RPM 3-CNF formula $\varphi$.

Figure 8.2: The matching $S_{\varphi}$ of the formula $\varphi$ from Figure 8.1.
just above the diagonal, in the inside of the rectangle. This red point is connected to the bottom right blue point. Similarly, we add one blue point on the same vertical, just below the diagonal. This blue point is connected to the top left red point.

We will refer to the triangle consisting of the three topmost points of a variable gadget as the top triangle of the variable gadget.

Lemma 8.3.1. A variable gadget is the starting matching of exactly two untangle sequences of length 1 , each untangle sequence ending in a distinct matching.

Proof. It is straightforward to check the two possible cases.

We can therefore represent each variable $x$ of a propositional formula by a variable gadget. Assigning $x$ to a truth value amounts to choosing one of the two possible untangle sequences, with the convention that the lower edge of the rectangle is present in the final matching if $x=1$ (i.e., $x$ is "true"), and that the upper edge of the rectangle is present if $x=0$ (Figure 8.3).

Figure 8.3: A variable gadget and its two untangle sequences.

### 8.4 OR Gadgets

An $O R$ gadget consists of four three-segment matchings built on a common point set, say $\left\{r_{1}, r_{2}, r_{2}^{\prime}, r_{3}\right\}$ for the red points, and $\left\{b_{1}, b_{1}^{\prime}, b_{2}, b_{3}\right\}$ for the blue points, as follows (see the first matching in each of Figures 8.4(a), 8.4(b), 8.4(c), and 8.4(d), ignoring the dashed segments). The $0 \vee 0$ matching consists of the segments $r_{1} b_{1}^{\prime}, r_{2}^{\prime} b_{2}, r_{3} b_{3}$, and only the first two are not crossing. The $0 \vee 1$ matching consists of the segments $r_{1} b_{1}^{\prime}, r_{3} b_{3}, r_{2} b_{2}$, and only the first two are crossing. The $1 \vee 0$ matching consists of the segments $r_{2}^{\prime} b_{2}, r_{3} b_{3}, r_{1} b_{1}$, and only the first two are crossing. The $1 \vee 1$ matching consists of the segments $r_{1} b_{1}, r_{2} b_{2}, r_{3} b_{3}$, and is crossing-free. In addition to these constraints, the point set also satisfies the following ones. The following three matchings are crossing-free: $\left\{r_{1} b_{2}, r_{2}^{\prime} b_{3}, r_{3} b_{1}^{\prime}\right\},\left\{r_{1} b_{3}, r_{2} b_{2}, r_{3} b_{1}^{\prime}\right\}$, and $\left\{r_{1} b_{1}, r_{2}^{\prime} b_{3}, r_{3} b_{2}\right\}$. In each of the following two matchings, only the first two segments are crossing: $\left\{r_{1} b_{3}, r_{2}^{\prime} b_{2}, r_{3} b_{1}^{\prime}\right\}$, and $\left\{r_{1} b_{1}^{\prime}, r_{3} b_{2}, r_{2}^{\prime} b_{3}\right\}$.

Figure 8.4: The four matchings of an OR gadget, with their untangle sequences.
Note that, in any of the four matchings of an OR gadget, there is one unused blue point and one unused red point. If the unused blue point is $b_{1}$ (respectively $b_{1}^{\prime}$ ), we
say that the left input of the OR gadget is 0 (respectively 1 ). Similarly, if the unused red point is $r_{2}$ (respectively $r_{2}^{\prime}$ ), we say that the right input of the OR gadget is 0 (respectively 1). To complete the similarity with a logical gate, we also define the output of the OR gadget as 0 if the segment $r_{1} b_{2}$ is present in all the final matchings of any untangle sequence starting at the OR gadget and as 1 if the segment $r_{1} b_{2}$ is absent of all the same final matchings. The output is undefined otherwise. The following lemma states that the truth table of the logical gate associated with an OR gadget is indeed the one of an OR gate.

We will refer to the smallest of the triangles consisting of the segment $r_{1} b_{2}$ and induced by all the other segments we have mentioned in the definition of an OR gadget as the top triangle of the OR gadget. It is the shaded triangle in Figure 8.4(d).

Lemma 8.4.1. The output of an OR gadget is always well defined, and is 0 if and only if the two inputs of the OR gadget are both 0 . More precisely, we have the following.

1. The $0 \vee 0$ matching is the starting matching of exactly two untangle sequences, each of length 2, and ending at the same matching containing the upper segment $r_{1} b_{2}$ (Figure 8.4(a)).
2. The $0 \vee 1$ matching is the starting matching of a unique untangle sequence of length 1 ending at a matching excluding the upper segment $r_{1} b_{2}$ (Figure 8.4(b)).
3. The $1 \vee 0$ matching is the starting matching of a unique untangle sequence of length 1 ending at a matching excluding the upper segment $r_{1} b_{2}$ (Figure 8.4(c)).
4. The $1 \vee 1$ matching is already crossing free. It excludes the upper segment $r_{1} b_{2}$ (Figure 8.4(d)).

Proof. For each of the four $x \vee y$ matchings with $x, y \in\{0,1\}$, we enumerate all the possible untangling sequences. These sequences are all shown in Figure 8.4. Lemma 8.4.1 then follows.

### 8.5 Clause Gadgets

A clause gadget consists of two OR gadgets, the output of the first one being "connected" to the left input of the second one (Figure 8.5). More precisely, a clause gadget is built on seven red points, say $r_{4}, r_{5}, r_{6}, r_{7}, r_{8}, r_{10}, r_{11}$, and six blue points, say $b_{4}, b_{5}, b_{6}, b_{7}, b_{8}, b_{9}$ such that the following maps correspond to two OR gadgets (using the OR gadget previous notations), and such that $r_{8}$ lie in the inside of the top triangle of the first OR gadget and is the only overlap between the two OR gadgets.

First OR gadget: $\left(r_{4}, b_{4}, r_{5}, b_{5}, r_{6}, b_{6}, b_{9}, r_{10}\right) \mapsto\left(r_{1}, b_{1}, r_{2}, b_{2}, r_{3}, b_{3}, b_{1}^{\prime}, r_{2}^{\prime}\right)$.
Second OR gadget: $\left(r_{4}, b_{6}, r_{7}, b_{7}, r_{8}, b_{8}, b_{5}, r_{11}\right) \mapsto\left(r_{1}, b_{1}, r_{2}, b_{2}, r_{3}, b_{3}, b_{1}^{\prime}, r_{2}^{\prime}\right)$,
with the exception that the segment $r_{6} b_{5}$ may also play the role of $r_{1} b_{1}$.
Similarly to an OR gadget, a clause gadget consists of $2^{3}$ matchings, namely the $x \vee y \vee z$ matchings with $x, y, z \in\{0,1\}$. We define the left, middle, and right input of a clause gadget as the left input of the first OR gadget, the right input of the first OR
gadget, and the right input of the second OR gadget. We define the output of a clause gadget as the output of the second OR gadget.

Note that the middle input segment, i.e., the vertical segment lying in between the two other vertical segments ( $r_{5} b_{5}$ in Figure 8.5), need not be evenly placed between the left input segment and the right input segment. This feature is used to build clause gadgets with non-consecutive variables, such as the topmost clause gadget in Figure 8.2.

The idea is to have a $0 \vee 0 \vee 0$ clause gadget in $S_{\varphi}$ for each clause in $\varphi$. As we will see next, in the beginning of an untangling sequence starting at $S_{\varphi}$, each input may be set to 1 or may be kept as 0 , changing the $0 \vee 0 \vee 0$ clause gadget into one of the $x \vee y \vee z$ matchings with $x, y, z \in\{0,1\}$.

The following lemma states that the truth table of the logical gate associated with a clause gadget is indeed the expected one.

Figure 8.5: A clause gadget. The $0 \vee 0 \vee 0$ matching is drawn with plain segments.

Lemma 8.5.1. The output of a clause gadget is always well defined, and is 0 if and only if the three inputs of the clause gadget are all 0 . More precisely, we have the following.

1. All the untangle sequences starting at the $0 \vee 0 \vee 0$ matching are of length 4 , and they end at the same matching containing the upper segment $r_{4} b_{7}$.
2. All the untangle sequences starting at each of the $x \vee y \vee z$ matchings, where exactly one of $x, y$, or $z$ is 1 , are of length 2 , and they end at matchings excluding the upper segment $r_{4} b_{7}$.
3. The unique untangle sequence starting at each of the $x \vee y \vee z$ matchings, where exactly two of $x, y$, and $z$ are 1 , is of length 1 , and it ends at a matching excluding the upper segment $r_{4} b_{7}$.
4. The $1 \vee 1 \vee 1$ matching is already crossing free, and it excludes the upper segment $r_{4} b_{7}$.

Proof. It is a consequence of Lemmas 8.4 and of the fact that the OR gadgets are connected so as to not interfere. Indeed, by construction, $r_{8}$ lies in the inside of the top triangle of the first OR gadget, and is the only overlap between the two OR gadgets. This ensures that all untangle sequences never give rise to an extra crossing that does not already belong to one of the two OR gadgets. In Figure 8.5, we have drawn with dashed line segments all the possible created segments during any possible untangle sequence.

### 8.6 Padding Gadgets

Let $k$ be a non-negative integer. A $k$-padding gadget triggered by the segment $s$ consists of two matchings built by induction as follows.

The first matching, denoted $S_{k}$, contains $s\left(s=r_{4} b_{7}\right.$ in Figure 8.6) and is called the triggered matching of the padding gadget ( $s$ creates a crossing). The second matching is called the non-triggered matching, and is deduced from the triggered one by removing $s$ (it is crossing free).

Figure 8.6: The triggered matching of a padding gadget.
If $k=0$, then the triggered matching of a $k$-padding gadget consists of only the segment $s$. If $k \geq 1$, then the triggered matching of a $k$-padding gadget consists of $S_{k-1}$, the triggered matching of a $(k-1)$-padding gadget, to which we add one new segment crossing only the last created segment of the only untangle sequence starting at $S_{k-1}$ (Figure 8.6, the dashed segments are all the possible created segments in the unique untangle sequence).

Lemma 8.6.1. Let $k$ be a non-negative integer. There exists a unique untangle sequence starting at the triggered matching of a padding gadget, and its length is $k$. The nontriggered matching of a padding gadget is already crossing free.

Proof. The definition of a $k$-padding gadget yields Lemma 8.6.1.
We complete each clause gadget with a padding gadget in order to penalize a non-satisfied clause by an arbitrary long untangle sequence (Figure 8.7). Notice that a padded clause gadget can be arbitrarily scaled and that the position of a clause rectangle is only constrained by the planar embedding of $\varphi$.

Figure 8.7: A clause gadget connected to a padding gadget.

### 8.7 Matching Computation

We now describe, given a planar embedding of $\varphi$, the construction steps of the matching $S_{\varphi}$. Without loss of generality, we only specify the construction of the positive clauses, the construction of the negative clauses being similar.

We need the following definitions for the description. The top vertical points of a positive clause gadget are the topmost endpoints of the vertical segments (e.g. $b_{14}, r_{4}, r_{12}, b_{5}, b_{7}$ in Figure 8.8). Similarly, the bottom vertical points are the bottom endpoints of the same vertical segments (e.g. $r_{14}, b_{4}, b_{12}, r_{5}, r_{7}$ in Figure 8.8). Let $\bar{p}$ be a top vertical point. The horizontal segment of $\bar{p}$ is the horizontal segment lying below $\bar{p}$ which is the closest to $\bar{p}$. Finally, we define the substitute point of $\bar{p}$ as the endpoint of the horizontal segment of $\bar{p}$ which is the closest to $\bar{p}$ (e.g. $r_{6}$ is the substitute point of $r_{4}$ in Figure 8.8).

The construction steps of the matching $S_{\varphi}$ are the following.

1. Place a clause gadget connected to a $k$-padding gadget in each clause rectangle, and a variable gadget in each variable rectangle, with appropriate scaling.
2. Connect each clause gadget to its corresponding three variable gadgets with the three vertical segments of the clause gadget aligned with the corresponding vertical edges of the planar embedding of $\varphi$.
3. Adjust the $x$-coordinates of the vertical segments of each variable gadget to have the top vertical points and the two topmost points of the variable gadget, all in convex position (e.g. in Figure 8.8, $r_{12}$ is on the right of the segment $r_{4} b_{9}$ ).
4. Adjust the $y$-coordinates of the bottom vertical points in the top triangle of each variable gadget so as to place them and the two topmost points of the variable gadget in convex position.
5. Let $\bar{p}$ be a top vertical point which is not the highest of a variable gadget (e.g. $\bar{p}=r_{12}$ in Figure 8.8). Let $\underline{p}$ be the corresponding bottom vertical point (e.g. $\left.\underline{p}=b_{12}\right)$. Let $\bar{q}$ be the top vertical point immediately above $\bar{p}\left(\right.$ e.g. $\left.\bar{q}=r_{4}\right)$. Let $\underline{q}^{\prime}$ be the point immediately above $\underline{p}$, taken among the bottom vertical points together with the two topmost points of the variable gadget (e.g. $q=b_{9}$ ). Adjust the $x$-coordinate of $\tilde{p}$, the substitute point of $\bar{p}$ (e.g. $\tilde{p}=r_{13}$ ), so that $\tilde{p}$ lies in the triangle $\bar{p} q \bar{q}$ (e.g. a shaded triangle in Figure 8.8; segment $r_{13} b_{13}$ must not cross $r_{4} b_{9}$, but $\overline{\text { it }}$ has to cross $r_{12} b_{9}$ ).

We have the following lemma.
Lemma 8.7.1. Let $\varphi$ be an instance of RPM 3-SAT with c clauses and $v$ variables. Let $k$ be a non-negative integer, polynomial in $c$ and $v$. The matching $S_{\varphi}$ with $k$-padding gadgets is computed in polynomial time in $c$ and $v$.

Proof. The number of operations in any execution of these construction steps is linear in $c$ and $v$. The coordinates of the points of $S_{\varphi}$ are rational numbers with $O(\log n)$ bits.

Figure 8.8: A padded clause gadget connected to $x, y, z$, with branching on $x$.

### 8.8 Branching

The following lemma ensures that the connection of multiple vertical segments to a same variable gadget always triggers all the corresponding clause gadgets. We start with some definitions.

The set consisting of the top segment of a variable gadget set to true, together with the vertical segments crossing it, and their horizontal segment is called a branching matching (such as drawn in Figure 8.9(b) with plain segments). The bottom vertical points of a branching matching, listed from left to right, always consist of a certain number, say $a$, of red points followed by a certain number, say $b$, of blue points. We say that such a branching matching has parameters $a, b$. These matchings have the following property.

Lemma 8.8.1. All the untangle sequences starting at a branching matching with parameters $a, b$ have length $2(a+b)$ and end at the same crossing-free matching (e.g. the segments $r_{15} b_{14}, r_{9} b_{15}, r_{14} b_{4}, r_{4} b_{6}, r_{6} b_{12}, r_{12} b_{13}, r_{13} b_{9}$ in Figure 8.9(b)).

Proof. First note that a simplified version of this result has been proven in Theorem 3.2.12 [19]. This simplified version amounts to forget all the horizontal segments, except the top segment of the variable gadget (Figure 8.9(c)).

It is useful to start by proving this simplified version before Lemma 8.8.1. We do an induction on $a+b$. The base case is trivial, but it provides the possible positions of created segments in the untangle sequences (the dashed segments in Figure 8.9(c)). The inductive case relies on the fact that the points are in convex position. Indeed, after any flip, the two created segments play the role of the initial horizontal segment because convex position ensures that any of the non-flipped vertical segments will cross exactly one of the two created segments, and that no extra crossing is created. The induction hypothesis then applies on both right and left submatching whose convex hulls are now disjoint.

Figure 8.9: Three views of a branching matching.

We now address the issue where each vertical segment is paired with its horizontal segment. Recall that at step 5 of the construction of $S_{\varphi}$, we have adjusted the $x$ coordinate of $\tilde{p}$, the substitute point of each top vertical point $\bar{p}$, so that $\tilde{p}$ lies in the triangle $\bar{p} q \bar{q}$. This ensures that each substitute point can play the role of its corresponding top vertical point from whenever the corresponding horizontal segment has been flipped in an untangle sequence.

### 8.9 Result

The RPM 3-SAT instance being encoded in the matching $S_{\varphi}$, we have the property that the shortest untangling sequence of $S_{\varphi}$ is short if the instance $\varphi$ is satisfiable, and long otherwise.

Lemma 8.9.1. We have the following case distinction.

- $\varphi$ is satisfiable if and only if there exist untangle sequences starting at $S_{\varphi}$ which do not trigger any padding gadget, in which case $d\left(S_{\varphi}\right)$ is at most $v+5 c$.
- $\varphi$ is not satisfiable if and only if all untangle sequences starting at $S_{\varphi}$ trigger at least one padding gadget, in which case $d\left(S_{\varphi}\right)$ is at least $v+7+k$ where $k$ is arbitrarily large.

Proof. It is consequence of Lemmas 8.3.1, 8.5.1, 8.6.1 and 8.8.1, as we examine the longest possible untangle sequences of $S_{\varphi}$ which do not trigger any padding gadget, and the shortest possible untangle sequences of $S_{\varphi}$ which trigger at least one padding gadget. In any case, $v$ flips will be performed, one per variable (Lemma 8.3.1).

In the case where no padding gadget is triggered, the length of the longest possible untangle sequences starting at a clause gadget connected to three variable gadgets is 5 , and is obtained by adding 3 , the length of the untangle sequences of a $0 \vee 0 \vee 1$ matching, and 2 , for the two connections to the negative variables. Counting 5 flips per clause yields $v+5 c$.

If at least one padding gadget is triggered, this very padding gadget generates $k$ flips. In this case, the length of the shortest possible untangle sequences starting at a clause gadget connected to three variable gadgets and which is known to trigger its padding gadget is 7 , and is obtained by adding 4 , the length of the untangle sequences of a $0 \vee 0 \vee 0$ matching, and 3 , for the three connections to the negative variables. All the other cause gadgets may be set to their $1 \vee 1 \vee 1$ matching, adding no flip to the shortest untangle sequence, the length of which is thus $v+7+k$.

We now prove Theorem 8.0.1, reducing RPM 3-SAT to Problem 1. Let $\varphi$ be an instance of RPM 3-SAT with $c$ clauses and $v$ variables. We build the matching $S_{\varphi}$, which serves as an instance of Problem 1, choosing $k=\alpha(v+5 c)+1$. As $k$ is polynomial in the size of the input ( $\alpha$ is a constant), the computation of the matching $S_{\varphi}$ is polynomial (Lemma 8.7.1).

By hypothesis, we compute an untangle sequence starting at $S_{\varphi}$ of length $\ell$ at most $\alpha d\left(S_{\varphi}\right)$. We decide that $\varphi$ is satisfiable if $\ell \leq \alpha(v+5 c)$, and that $\varphi$ is not satisfiable if $\ell>\alpha(v+5 c)$.

Indeed, Lemma 8.9.1 ensures the following. If $\varphi$ is satisfiable, then the length of the shortest untangle sequence of $S_{\varphi}$ is at most $v+5 c$. Otherwise the length of the shortest sequence is at least $v+7+k \geq k=\alpha(v+5 c)+1$. This ends the reduction, and proves Theorem 8.0.1.

## Chapter 9

## Conclusion

This chapter is less a conclusion to this dissertation than an introduction to possible future developments. For each choice (i.e., for no choice, removal choice, insertion choice, and both choices) and for intractability, we explain the difficulties to extend or improve known results sometimes providing counter-examples to some intuitive ideas, we present some open problems which might be stepping stones to tackle the main open problems, and we discuss about what we believe could be promising ideas.

### 9.1 Untangling with No Choice

When no choice is available, the only approach so far has been to find "good" potentials to measure how far a multiset of segments is from being crossing free. To specify what "good" means, we define (in the $\Pi$ version for some property $\Pi$ ) the faithful potential of a multiset $S$ of segments $\mathbf{d}_{\Pi}^{\emptyset}(S)$ as the length of longest untangle sequence of $S$. Obviously, $\mathbf{d}_{\Pi}^{\emptyset}(S)$ decreases by at least one at each flip, and any other potential does not provide a better upper bound than $\max _{S} \mathbf{d}_{\Pi}^{\emptyset}(S)$. The issue is then to prove a good upper bound on $\mathbf{d}_{\Pi}^{\natural}(S)$. Now, we see that a good potential is one that is as close to the faithful potential as possible while still admitting a good upper bound for which we have a proof. In the following, we first present some variations of the potentials used in the previous chapters with some of their interesting consequences.

The potential of one point. The potential of a point $p \in P$ is defined as the sum of the potentials of the lines through $p$, i.e., the sum of the $\Lambda_{p p^{\prime}}$ for all $p^{\prime} \in P \backslash\{p\}$ ( $\Lambda$ is defined just before Lemma 3.1.1 [83]). This potential shows that the point $p$ is involved in at most $n^{2}$ flips in an untangle sequence. Using the fact that there is a zone defined by each flip $f$ such that all the points both in $P$ and in this zone define $f$-critical lines (see the proof of Theorem 4.3.1 [30] for the definition of an $f$-critical line, see Lemma 4.5.3 [30] for another use of this fact), we can show that a ray from $p$ containing the segment adjacent to $p$ and rotating in the direction minimizing its angle of rotation sweeps at most $n^{2}$ points of $P$ in an untangle sequence.

The potential of two points. There are three alternatives to define the potential of two points.

The potential of two points $p_{1}, p_{2}$ may be defined as the potential of the line $p_{1} p_{2}$, i.e., $\Lambda_{p_{1} p_{2}}$. This potential decreases by at least 1 at each flip removing the segment $p_{1} p_{2}$ and takes at most $n$ distinct values, thus proving that a given segment is removed at most $n-1$ times (and inserted at most $n$ times).

Similarly, the potential of two points $p_{1}, p_{2}$ may be defined as the sum of the potentials of two lines crossing the segment $p_{1} p_{2}$ which are close enough to the line $p_{1} p_{2}$. This potential decreases by at least 2 at each flip removing the segment $p_{1} p_{2}$ and takes at most $2 n-1$ distinct values, thus proving that a given segment is removed at most $n-1$ times (and inserted at most $n$ times). This potential proved handy in the proof of Theorem 3.1.3 to cope with the absence of any general position assumption.

Alternatively, the potential of two points $p_{1}, p_{2}$ may be defined as the sum of the potentials of two lines being close enough to the line $p_{1} p_{2}$ while being parallel to $p_{1} p_{2}$. This potential decreases by at least 2 at each flip inserting the segment $p_{1} p_{2}$ and takes at most $2 n-1$ distinct values, thus proving that a given segment is removed at most $n-1$ times (and removed at most $n$ times). This potential is introduced in [19] to prove Theorem 3.1.3 in the Matching version (assuming general position).

The potential of one segment. In the Convex version, we may define the potential of one segment $s$ of $S$ as the number of segments of $S$ crossing $s$. We have found no way to generalize this type of potential to the non-Convex versions.

The potential of a convex partition. Note that a line defines a convex partition of the plane. One idea is to try to define a potential of a convex partition which is not necessarily induced by a line. Our tries all led to functions increasing in some flip situations.

A potential based on the cyclic order of the points. The potential $\Phi$ based on the cyclic order of $P \backslash\{p\}$ around each point $p$ used in the proof of Theorem 4.4.1 in the Redonaline version is very interesting. Indeed, the idea is to see untangling as a generalisation of sorting. Moreover, counting the number of points in $P$ that "see" a given T-pair as an X-pair provides a "measure" of how much this T-pair is from being $\mathbf{X}($ or $\mathbf{H})$. For instance, this observation can be used to relax the requirement that the removed segments cross in the definition of a flip to the requirement that less points in $P$ "see" the inserted pair has an X-pair than the removed pair. Unfortunately, the potential $\Phi$ does not generalise well to the other versions. A possible reason is that the point set order type (see Section 1.5 for the definitions of the order type and crossing type of a point set) is not determined by this list of cyclic orders (see [5] for a reconstruction of all the order types of a given list of cyclic orders). It seems also unlikely that the point set crossing type would be determined by this list of cyclic orders (see for example [73] for an algorithm reconstructing the crossing type of a point set from its planar spanning trees organised in a reconfiguration graph).

A potential based on state tracking. As we have seen in Section 5.8, the state tracking framework sheds a new light on the untangling problems. For instance, it is possible to see the line potential $\Lambda_{L}$ (where $L$ is the set of the lines defined by any pair of points in the point set $P$ ) as counting the transitions $\mathbf{X} \rightarrow \mathbf{H}$. In fact, $\Lambda_{L}$
also decreases by at least one for each $\mathbf{H} \rightarrow \mathbf{T}$ and each $\mathbf{T} \rightarrow \mathbf{X}$ (via critical lines). As we already know that each X-pair may be flipped at least once, we may focus on counting how many times each pair is flipped beyond once. We may therefore hope that some lines in $L$ are not needed anymore if we focus on counting $\mathbf{H} \rightarrow \mathbf{T}$ (or $\mathbf{T} \rightarrow \mathbf{X}$ ) transitions instead of $\mathbf{X} \rightarrow \mathbf{H}$. Unfortunately, all the lines are needed in general. In the Bipartite version, only the lines defined by to points of $P$ of the same color are needed (instead of the lines defined by to points of $P$ of different colors), but their number is still quadratic, leading to the same cubic upper bound again. In fact, in the context of bounds parameterized by $t$, the first proof of Theorem 4.3.1 was found in the case where the points of $T$ are inside the convex hull of $C$ using the state tracking approach to count $\mathbf{H} \rightarrow \mathbf{T}$ transitions with fewer lines than in $L$.

Searching head-on for good potentials is one strategy. In the following, we present interesting remarks which are less focused on potentials.

The crossing type of a flip sequence. Similarly to the crossing type of a point set, we define the labeled crossing type of a flip sequence as the set of the pairs of pairs of labels of points which corresponds to the set of pairs of segments which are removed at some point in the flip sequence. Two flip sequences have the same crossing type if there exists a relabeling of the points such that the two flip sequences have the same labeled crossing type. This definition is useful to realize that

- a lot of the flip sequences we may come up with have the same crossing type (hence at most a quadratic length) as a flip sequence with endpoints in convex position,
- when we are only interested in some multisets of segments on a given point set, the problem depends only on the union of the crossing types of all the flip sequences of the multisets of interest (which may be even less constrained than the crossing type of the point set itself).

The intuition that all the flip sequences have the same crossing type as some flip sequence with endpoints in convex position is disproved by Theorem 4.2.1.

Reductions. In Lemma 2.3.1, Lemma 2.3.2, Lemma 2.3.3, and Theorem 4.1.1, we showed a relationship among different versions of $\mathbf{d}^{\emptyset}$. The latter result shows how upper bounds in the Matching version can be easily transferred to different versions. But they can also be applied to transfer lower bounds among different versions. For example, the lower bound of $\frac{3}{2}\binom{n}{2}-\frac{n}{4}$ in the Bipartite Matching version from Theorem 4.2.1 [33] implies a lower bound of $\frac{1}{3}\binom{n}{2}-\frac{n}{2}$ in the Cycle version. It is not clear if the constants in the Cycle version lower bound may be improved, perhaps by a more direct approach (or perhaps the lower bounds are not even asymptotically tight). However, we showed that all these versions are related by constant factors.

Upper bound without multiplicity. The upper bound from Theorem 4.5.1 on the number of distinct flips may be useful if one of the following open problems is solved.

- What is the maximal multiplicity of a flip removing a given segment $p_{1} p_{2}$ in an untangle sequence? We know that it is at most $n-1$ thanks to the line potential $\Lambda_{p_{1} p_{2}}$. Any sub-linear upper bound would lead to a sub-cubic upper bound on $\mathbf{d}_{\text {Multigraph }}^{0}$.
- Is it possible to devise a removal strategy which guaranties that the multiplicity of each flip is sub-linear? A yes would improve the cubic upper bound on $\mathbf{d}_{\text {Multigraph }}^{\mathrm{R}}$.

The proof of Theorem 4.5.1 is based on the $O\left(n^{2} k^{2}\right)$ bound from Lemma 4.5.3. A better analysis of the dual arrangement could potentially improve this bound, perhaps to $O\left(n^{2} k\right)$.

An inductive approach. If we add a new segment to a crossing-free multiset of segments, what is the maximum length of an untangle sequence? Notice that a subquadratic bound would lead to a sub-cubic bound for $\mathbf{d}_{\text {Multigraph }}^{\natural}$.

A tight quadratic lower bound. All our small scale experiments have so far shown that the quadratic lower bound seems to be asymptotically tight. Specifically in the Bipartite version, all our small scale experiments have so far shown that the lower bound of Theorem 4.2.1 seems to be exactly tight for even $n$. Apparently, bipartite matchings with endpoints in general position do not lead to untangle sequences longer than in the Redonaline version.

### 9.2 Untangling with Removal Choice

Devising removal strategies is strongly related to the motivation of untangling TSP tours. In this section, we discuss about lower bounds, what to do with the results in the Redonaline version, how counting flips without multiplicity could become useful, a recursive approach, the irregular dependencies in $t$ in parameterized bounds, and last but not least we present work in progress involving state tracking to prove a quadratic upper bound on $\mathbf{d}_{\text {Bipartite Matching }}^{\mathrm{R}}$.

A tight linear lower bound. All our small scale experiments have so far shown that the linear lower bound seem to be asymptotically tight. In the following, we forget about this remark to discuss about how to prove lower bounds.

First note that most of the removal strategies are not known to be optimal. In fact, only the Convex version algorithms are shown to have optimal worst case flip complexity, except in the Multigraph version. It is uncertain whether the $O(n \log n)$ upper bound or the linear lower bound on $\mathbf{d}_{\text {Convex Multigraph }}^{\mathrm{R}}$ can be improved. Besides, in the Convex Bipartite version, there are hints (explained in Section 9.5, see footnote ${ }^{3}$ ) for the lower bound of Theorem 5.1.1 to be exactly tight for even $n$.

Improving the lower bound amounts to devising a strategy in place of the adversary, using insertion choice to make the untangle sequence as long as possible. As some multisets of segments do not admit untangle sequence with super-linear length, the choice of the initial multiset of segments is important. Moreover, to fully benefit from this choice, we have to use insertion choice to decrease as little as possible a potential
for which we know a high lower bound on its initial value and an low upper bound its the final value. The only three potentials known to have a low upper bound on crossing-free multisets of segments (in fact, they all equal 0 on crossing-free multisets) are the number of crossings $\chi$ and the sum, or the product, of the crossing depths $\delta_{\times}(s)$ of the segments $s$ in the multiset (the potential involving the crossing depths are specific to the Convex version). There are flip situations where both insertion choices lead to a big decrease of any of these three potentials. For instance, the potential $\chi$ decreases by $n-2$ for any flip of a multiset having each of its segments crossing all its others (with endpoints in convex position). Avoiding these situations or proving that they are not frequent (for example, by a similar argument than in the proof of Theorem 6.1.1 [31]) would lead to a lower bound on $\mathbf{d}_{\text {Convex }}^{\mathrm{R}}$ Multigraph .

From the Redonaline version to generalizations. Generalizing the algorithm used in the proof of Theorem 3.3.1 to bipartite point sets with the red points below the $x$-axis and the blue points above using ray shooting ideas to generalize the path $u$ did not work. ${ }^{1}$

Generalizing the algorithm used in the proof of Theorem 5.8.1 did not work either as Lemma 5.8.3 relies on the red-on-a-line setting. It may generalize to some deformation of this setting like red-on-a-convex for instance.

Upper bound without multiplicity. Recall that a removal strategy which guaranties that the multiplicity of each flip is sub-linear together with the upper bound from Theorem 4.5.1 on the number of distinct flips may improve the cubic upper bound on $\mathbf{d}_{\text {Multigraph }}^{\mathrm{R}}$.

A recursive approach. A recursive removal strategy which untangles a new segment added to a crossing-free multiset of segments in sub-quadratic time would lead to a sub-cubic bound for $\mathbf{d}_{\text {Multigraph }}^{\mathrm{R}}$.

The dependency on $t$. In the upper bound of Theorem 5.5.2 [31] which appears to be exactly the same as the upper bound of Theorem 5.7.1 [31], the quadratic dependency on $t$ provides a continuous transition between the upper bounds in the Convex versions (as in Theorem 5.2.1) and the cubic upper bound for general point sets from Theorem 3.1.3. The fact that the proof Theorem 5.5.2 [31] independently leads to the same upper bound as the proof of Theorem 5.7.1 [31] may be in itself a hint for some unified proof. In the upper bounds of Theorem 5.4.2 [31] and Theorem 5.6.1 [31], the linear dependency on $t$ would provide a continuous transition between the upper bounds in the Convex versions (as in Theorem 5.2.1) and a conjectured quadratic upper bound for general point sets (see the next paragraph "State tracking to prove a quadratic upper bound on $\mathrm{d}_{\text {Bipartite Matching }}^{\mathrm{R}}$.").

State tracking to prove a quadratic upper bound on $\mathrm{d}_{\text {Bipartite Matching. }}^{\mathrm{R}}$. The author believe it is possible to use state tracking to prove a quadratic upper bound on $\mathrm{d}_{\text {Bipartite Matching. }}^{\mathrm{R}}$. Next, we provide some insight on this intuition.

[^19]As we have seen in the proof of Theorem 3.2.1, there is a correspondence between the permutations of $n$ elements and the bipartite matchings on a given bipartite point set where the red (respectively blue) points are labeled $r_{1}, \ldots, r_{n}$ (respectively $\bar{r}_{1}, \ldots, \bar{r}_{n}$ ). Specifically, a bipartite matching $S$ defines a permutation $\sigma$ where, for each segment $r_{a} \bar{r}_{b}$ in $S, a$ is mapped to $b$. For such a bipartite matching, the flips correspond to a subset of the transpositions. Specifically, a flip (in the Bipartite version) removing the segments $r_{a} \bar{r}_{b}, r_{c} \bar{r}_{d}$ corresponds to the transposition (ac) (i.e. the transposition mapping $a$ to $c$ and vice versa). A flip sequence $\left(S_{i}\right)_{i \in\{0, \ldots, k\}}$ corresponds to a sequence of permutations, say $\left(\sigma_{i}\right)_{i \in\{0, \ldots, k\}}$, and the associated sequence of flips corresponds to a sequence of transposition, say $\left(\tau_{i}\right)_{i \in\{1, \ldots, k\}}$, such that for all $i \in\{1, \ldots, k\} \sigma_{i-1} \tau_{i}=\sigma_{i}$.

Two transpositions do not commute unless they are identical or they operate on disjoint subsets of $\{1, \ldots, n\}$. Yet, we may swap two transpositions in a wicker sense, preserving at least one of them. Specifically, for all distinct four integers $a, b, c, d$ in $\{1, \ldots, n\}$, we have the following identities from elementary algebra.

$$
\begin{align*}
(a b)(a b) & =\operatorname{Id}  \tag{9.1}\\
(a b)(c d) & =(c d)(a b)  \tag{9.2}\\
(a b)(b c) & =(c a)(a b)=(b c)(c a) \tag{9.3}
\end{align*}
$$

The idea is to transform any flip sequence (seen as a sequence of transpositions) into a flip sequence of length at most $\binom{n}{2}$ where the track of each pair of segments (i.e., the sequence of pairs of segments, each turning into the next one) is only flipped once. This may be achieved by iteratively choosing a flip $f$ in the sequence which is the second flip of its track and swapping the transposition $\tau$ corresponding to $f$ with the others transpositions (using (9.2) or (9.3)) to place $\tau$ next to its first occurrence in the track and cancel these to copies of $\tau$ (using (9.1)). The swapping of $\tau$ is guided by the track, i.e., choosing which of the two identities in (9.3) to use for a swap is done in order to "preserve" the states of the pairs of segments involved in the swap. It is still work in progress whether the final sequence of transposition we obtain is a flip sequence, but our experiments swapping the longest sequence known (starting with a butterfly, see Theorem 4.2.1) work well.

### 9.3 Untangling with Insertion Choice

It may be surprising that a quadratic upper bound is known on $\mathbf{d}_{\text {Multigraph }}^{\top}$ (Theorem 3.1.4 [19] and Theorem 3.1.5 [17]) but not on $\mathbf{d}_{\text {Multigraph }}^{\mathrm{R}}$ (where the best upper bound known is cubic in general, thanks to Theorem 3.1.3 [19, 82]). Insertion choice is indeed very different from removal choice; any simple reduction between the two seems unlikely. Next, we discuss about lower bounds, then about the recursive approach.

Lower bounds. We have not coded any experiments for insertion choice. In the following, we discuss about how to prove lower bounds nonetheless, with many aspect similar to lower bounds with removal choice.

Similarly to lower bounds with removal choice, proving a lower bound amounts to devising a strategy in place of the adversary, this time using removal choice to make the untangle sequence as long as possible. Again, the choice of the initial multiset of
segments is important. Again, to fully benefit from this choice, we have to use removal choice to decrease as little as possible a potential for which we know a high lower bound on its initial value and an low upper bound on its final value. Again, the only three potentials known to have a low upper bound on crossing-free multisets of segments are the number of crossings $\chi$ and the sum, or the product, of the crossing depths $\delta_{\times}(s)$ of the segments $s$ in the multiset. Recall that there are flip situations where both insertion choices lead to a big decrease of any of these three potentials. Avoiding these situations or proving that they are not frequent would lead to a lower bound on $\mathbf{d}_{\text {Convex }}^{\mathrm{I}}$ Multigraph .

As usual, the insertion strategies are not known to be optimal. Even in the Convex version, the algorithm from Theorem 6.1.1 providing an $O(n \log n)$ upper bound on $\mathbf{d}_{\text {Convex Multigraph }}^{\mathrm{I}}$ is not optimal. It is uncertain whether this $O(n \log n)$ upper bound or the linear lower bound on $\mathbf{d}_{\text {Convex Multigraph }}^{\mathrm{I}}$ can be improved. Regardless, if we set our mind to improve the lower bound, it may be a good approach to choose a multiset having each of its segments crossing all its others (with endpoints in convex position) as the starting multiset, and to use a similar removal strategy as in the proof of Theorem 5.2.1 [31]. Yet, it remains to prove that the crossing depth potentials do not decrease too much or too often.

The author's current belief is that $\mathbf{d}_{\text {Multigraph }}^{\mathrm{I}}$ is $\Theta(n \log n)$ (even in the non-Convex version). If, regardless of this intuition, we want to prove a lower bound on $\mathbf{d}_{\text {Multigraph }}^{\mathrm{I}}$ which is $\omega\left(n^{\frac{3}{2}}\right)$, a consequence of Theorem 3.1.5 [17] is that, we need a point set with a crossing type that admits no realisation with an $O(\sqrt{n})$ spread. In other words, we need to find a crossing type that is impossible to draw as a dense point set.

A recursive approach. Again, a recursive insertion strategy which untangles a new segment added to a crossing-free multiset of segments in sub-linear time would lead to a sub-quadratic bound for $\mathbf{d}_{\text {Multigraph }}^{\mathrm{I}}$.

### 9.4 Untangling with Both Choices

It is surprisingly not obvious how to take advantage of both choices to untangle segments when there is such a gap between the quadratic upper bound in general (Theorem 3.1.4 [19]) and the linear lower bound (Theorem 3.2.12). Next, we discuss about lower bounds, about the recursive approach, and about the intriguing only theorem specific to the Matching version.

A tight linear lower bound. As with removal choice, all our small scale experiments have so far shown that the linear lower bound seem to be asymptotically tight.

Regardless, proving a lower bound amounts to choosing an initial multiset of segments such that all its untangle sequences are long. This may be achieve similarly to the proofs of Theorem 3.2.12 and Theorem 5.1.1 using a flip invariant of some class of multiset of segments in which we have chosen the initial multiset.

A recursive approach. Once more, a recursive strategy for both choices which untangles a new segment added to a crossing-free multiset of segments in sub-linear time would lead to a sub-quadratic bound for $\mathbf{d}_{\text {Multigraph }}^{\mathrm{RI}}$.

The only theorem specific to the Matching version. It is intriguing that Lemma 7.2.1 [31], and thereby Theorem 7.2 .3 [31] are so far the only results specific to the Matching version which do not admit a straightforward generalization to the Multigraph version.

### 9.5 Intractability

Designing strategies to untangle segments with optimal worst case flip complexity is one thing, computing the shortest untangle sequence of each instance is another. This raises the problem of the complexity class of the latter. Theorem 8.0.1 shows that this problem is $\mathcal{N} \mathcal{P}$-hard in the Bipartite Matching version. Although a direct corollary of Theorem 8.0.1 is that the shortest untangle sequence (or any constant factor approximation of it) is also $\mathcal{N} \mathcal{P}$-hard in the Bipartite Multigraph version, it remains unclear how to prove intractability in any other versions. We have also consider proving the intractability of computing the longest untangle sequence of each instance. In the following, first we present ideas about why the shortest untangle sequence problem in the Convex Bipartite Matching version could possibly be in $\mathcal{P}$, then we explain the main difficulties we have encountered to prove the intractability of the shortest untangle sequence in other versions and of the longest untangle sequence, and we conclude by a remark about a hypothetical unified intractability proof.

The shortest untangle sequence in the Convex Bipartite Matching version. The proof of Theorem 8.0.1 relies on gadgets which do not have endpoints in convex position. In fact, it might not be the case that the shortest untangle sequence is $\mathcal{N} \mathcal{P}$-hard in the Convex Bipartite Matching version. ${ }^{2}$ In the following, we try to give some ideas for an algorithm to compute the shortest untangle sequence in the Convex Bipartite Matching version.

As in any Bipartite version, the segments of a bipartite matching $S$ (with end points in convex position) are oriented. Let us explicitly represent this orientation with arrows pointing from the red point to the blue point (Figure 9.1). Recall from the exhaustive version of the proof of Lemma 3.2.3 that $\chi(S)$, the total number of crossings in $S$, decreases by more than one in two specific situations (both corresponding to the rightmost case in Figure 5.3). Let us call these two situations the triangle situations. They consists in three pairwise crossing segments. One of the triangle situations occurs when the orientation of the three segments form an oriented cycle (if we cut off the portions of segments with no crossings and containing an endpoint). Let us call it the cyclic triangle situation (Figure 9.1(b)). The other triangle situation occurs when only two of the three segments form an oriented path. Let us call it the shortcut triangle situation (Figure 9.1(e)). In a cyclic triangle situation, flipping any two of the three segments leads to an extra drop of 2 in $\chi(S)$ (for instance, one of these three flips transforms Figure 9.1(b) into Figure 9.1(a)), while in a shortcut triangle situation, the only two segments leading to such a drop are the segments of the oriented path we mentioned (this flip transforms Figure 9.1(e) into Figure 9.1(d)).

Figure 9.1: Bipartite matchings with endpoints in convex position and segments decorated with an arrow pointing towards the blue point. The sequences (c)(b)(a), (f)(e)(d), and (h)(g) are flip sequences.
(a) \& (d) Crossing-free bipartite matchings.
(b) A cyclic triangle situation.
(c) \& (f) Quadrilateral situations.
(e) A shortcut triangle situation.
(g) A bipartite matching without $k$-gon situation.
(h) A dead-end quadrilateral situation.
(i) The circled crossing is both a good choice and a bad choice: its weight is $1-1=0$.

Note that the greedy removal strategy maximizing the decrease of the potential $\chi(S)$ is not well defined if there are no triangle situation; and there exists convex bipartite matchings with no triangle situation and with untangle sequences shorter than others (Figure 9.1(c) and Figure 9.1(f) show two examples).

The difficulty is that a triangle situation may be created only by flipping two segments forming an oriented path in what we call a quadrilateral situation (Figure 9.1(c) and Figure 9.1(f) may be flipped into Figure 9.1(b) and Figure 9.1(e)). Again, a quadrilateral situation may only come from a pentagon situation using the same type of oriented path segment flipping, and so on.

Generalizing, let the crossing graph of a bipartite matching $S$ be the directed graph whose vertices are crossing pairs of segments and such that there is an directed edge between two crossing pairs of segments if they share a segment (the orientation of this segment gives the orientation of the edge). Let $k$ be a positive integer at least 3. A $k$-gon situation occurs when the crossing graph of bipartite matching $S$ with endpoints in convex position admits a $k$-cycle such that non-adjacent vertices in the
$k$-cycle are also not adjacent in the crossing graph. If $k \geq 4$ and if the $k$-cycle of a $k$-gon situation admits a directed path of length 2 , then flipping the two corresponding segments transforms the $k$-gon situation into a $k-1$-gon situation. We say that a $k$-gon situation is a dead-end if no flip sequence transforms it into a triangle situation ( $k$ is then even). Figure 9.1(h) shows a dead-end quadrilateral situation; an example of a flip leads to Figure 9.1(g). ${ }^{3}$

Obviously, our algorithm should perform in priority the flips removing pairs of segments forming an oriented path in some polygon situation which is not a dead-end; let us call this type of removal choice a good choice. If there is no such pair, or if there is no polygon, then it is easy to prove that any untangle sequence uses as many flips as there are crossings in $S$. The question is how to choose the removed pair when there is more than one good choice, or when a choice is simultaneously good in a polygon situation and not good in another polygon situation. Moreover, there are also bad choices, i.e., choices breaking a $k$-gon situation which is not a dead-end; and a choice may be simultaneously good and bad (Figure 9.1(i)). This hints that we should weight each choice with the number of polygon situations making it a good choice minus the number of polygon situations making it a bad choice (in Figure 9.1(i), the circle crossing has a weight of 0 as it is involved as a good choice in exactly 1 quadrilateral situation and as a bad choice in exactly 1 quadrilateral situation; in fact 0 appears to be the maximum weight in this matching). Is remains to prove that the strategy prioritizing the removal choice with the highest weight indeed computes one of the shortest untangle sequences, and that it runs in polynomial time using some dynamic data structure.

The shortest untangle sequence in Redonaline Matching version. The proof of Theorem 8.0.1 relies on gadgets which do not have colinear red points. It is thus unclear whether reducing the rectilinear planar monotone 3-SAT problem is a good approach.

The shortest untangle sequence in non-bipartite versions. The proof of Theorem 8.0.1 takes advantage of the fact that the pair of segments inserted at a flip depends only on the color of the four endpoints involved and not on all the multiset of segments. This approach is not possible in the Cycle version, in the Tree version, or in the non-bipartite Multigraph version.

The longest untangle sequence. We have tried to reduce the Hamiltonian path problem in grid graphs (this problem is $\mathcal{N P}$-hard [58]) to the longest untangle sequence problem (in the Bipartite version). We did not succeed in building a gadget which transmits the untangling chained reaction to one of the outgoing edges of a vertex. The author's current intuition is that it is geometrically impossible to build such a gadget.

A unified intractability proof. If the shortest (respectively the longest) untangle sequence of a given multiset of segments is $\mathcal{N P}$-hard to compute in all the non-Convex

[^21]versions (as we currently believe), then it is likely that there exists a proof by reduction easily adaptable to all these versions.

### 9.6 Conclusion

In this dissertation, we have studied the problem of untangling segments in the plane, a reconfiguration problem with notable applications in TSP approximation algorithms. We have clarified and formalized a common framework based on the notion of choice to study the different versions of flips combining point set properties, degree properties, and insertion properties. We have gathered the fourteen results about untangling segments from the literature, generalizing many of them. Throughout eighteen theorems, we have proved several reductions between different versions, two counter-intuitive lower bounds, fourteen upper bounds, and one intractability result. We have used well-known techniques such as potentials, balancing arguments, preprocessing, induction, and divide and conquer, as well as new techniques such as state tracking. We have initiated a systematic study of point sets near convex position.

Our problematic on untangling segments in the plane is easy to state yet hard to solve; it is deeply related to crossing types and order types, an active field of research with many essential open problems. The special version of the problem where the endpoints form a convex polygon is well understood and nearly solved. However, for endpoints in general position, there remain striking gaps between quadratic lower bounds and cubic upper bounds on $\mathbf{d}^{\emptyset}$, between linear lower bounds and cubic upper bonds on $\mathbf{d}^{\mathrm{R}}$, and between linear lower bounds and quadratic upper bonds on $\mathbf{d}^{\mathrm{T}}$ and $\mathbf{d}^{\text {RI }}$. While we showed that the convex version does not always maximize the length of a flip sequence, the conjecture that the quadratic upper bounds on $\mathbf{d}_{\text {Convex }}^{\emptyset}$, the upper bounds on $\mathbf{d}_{\text {Convex }}^{\mathrm{R}}$ and $\mathbf{d}_{\text {Convex }}^{\mathrm{I}}$ (both $O(n \log n)$ or linear depending on the version), and the linear upper bounds on $\mathbf{d}_{\text {Convex }}^{\mathrm{RI}}$ asymptotically hold in the general version is still open. ${ }^{4}$

[^0]:    ${ }^{1}$ The author believes that doing mathematics consists in imagining anything as long as it helps understand something.
    ${ }^{2}$ The 2-dimension Euclidean TSP is $\mathcal{N} \mathcal{P}$-hard [58, 74]. The fastest known algorithm has a worst-case time complexity of $2^{O(\sqrt{n})}$ [35]. A $2^{o(\sqrt{n})}$ time algorithm does not exist unless ETH fails [35, 36].
    ${ }^{3}$ A non-exhaustive list of algorithms that might produce self-intersecting tours is: Nearest Neighbor, Greedy, Cheapest Insertion, Nearest Insertion, Farthest Insertion, Random Insertion, Minimum Spanning Tree, Christofides-Serdyukov $\frac{3}{2}$-approximation algorithm [26, 80], all the PTAS [10, 69, 76], and the probabilistic $\frac{3}{2}-\epsilon$-approximation algorithm [62, 78].

[^1]:    ${ }^{4}$ In fact, multisets of segments must be considered as a flip may insert another copy of an existing segment (Figure 1.2(a)).

[^2]:    ${ }^{5}$ This $n^{3}$ upper bound, shown for tours, easily generalizes to any multiset of segments.
    ${ }^{6}$ This $\frac{n(n-1)}{2}=O\left(n^{2}\right)$ lower bound is known for matchings with endpoints forming a convex polygon [19]; the reductions in Theorem 4.1.1 extend it to tours, trees, bipartite matchings, and to general multisets of segments.

[^3]:    ${ }^{7}$ In this case, computing the convex-hull of the point set yields the optimal tour in $n \log n$ time [12, 24], so the untangling process seems somewhat useless.
    ${ }^{8}$ In the case of general multisets of segments, the exact number of flips is $\frac{n(n-1)}{2}$, the number of pairs of segments.
    ${ }^{9}$ We use Hardy's notation $f(n) \preccurlyeq g(n)$ instead of the Bachmann-Landau notation $f(n)=O(g(n))$ in this chapter to ease the understanding of the non-specialist reader.

[^4]:    ${ }^{10}$ In particular, we do not consider properties such as "admitting a given coloring" where the given coloring has more than two colors.

[^5]:    ${ }^{11}$ Our bounds often have terms like $O(t n)$ and $O(n \log |C|)$ that would incorrectly become 0 if $t$ or $\log |C|$ is 0 . In order to avoid this problem, factors in the $O$ notation should be made at least 1. For example, the aforementioned bounds should be respectively interpreted as $O((1+t) n)$ and $O(n \log (2+|C|))$.

[^6]:    ${ }^{12}$ Other algorithms are asymptotically optimal in time, but not in space: the randomized ones are $[28,70]$, and the deterministic one is [25].
    ${ }^{13}$ Two other radomized algorithms, both based on the Bentley-Ottmann algorithm, additionaly require the segments to form a connected graph: one runs in $O\left(k+n \log ^{*} n\right)$ expected time [27], the other runs in $O\left(n+k \log ^{(i)} n\right)$ expected time for any constant $i$ [43]. In our context, this requirement is fulfilled for cycles and trees.

[^7]:    ${ }^{14}$ The variable $n$ always refers to the number of segments.
    ${ }^{15}$ The problem of computing crossing-free matchings has also been considered in higher dimensions [7]. The problem of computing minimal-weight perfect matching has been considered on arbitrary bipartite graphs instead of the complete bipartite graph [1].
    ${ }^{16}$ This repetition is not a typographic error, a segment being represented by an unordered pair of labels.

[^8]:    ${ }^{1}$ In particular, we do not consider properties such as "admitting a given coloring" where the given coloring has more than two colors.

[^9]:    ${ }^{2}$ The splitting definition may be refine even further in any version by considering in each $\binom{P_{i}}{2}$ only the segments which are inserted in at least one flip sequence of $S$.

[^10]:    ${ }^{3}$ This definition of uncrossable generalizes the one in [31].

[^11]:    ${ }^{1}$ The technical report [82] also appeared in a workshop [83].
    ${ }^{2}$ However, the paper [82] is not cited in [19], hinting that they perhaps rediscovered the result independently.

[^12]:    ${ }^{3}$ In [19], lines parallel to $p_{1} p_{2}$ are used instead. This choice does not work well if general position is not assumed.

[^13]:    ${ }^{4}$ In [82], the set of the lines $p_{1} p_{2}$ for all pairs of points $p_{1}, p_{2} \in P$ is used instead. This choice leads to a more tedious analysis if general position is not assumed. However, if general position is assumed, the analysis is smooth and the upper bound slightly improves to $\frac{1}{2} n\left(\binom{|P|}{2}-2|P|-3\right)$ (a given segment does not cross the $2|P|-3$ lines containing at least one of its endpoints). Moreover, in the Bipartite Matching version, the lines defined by a red point and a blue point suffice, further improving the upper bound to $\binom{n}{2}(n-1)$.

[^14]:    ${ }^{5}$ An alternative would be the intrinsic spread defined as the ratio between the maximum and the minimum area among triplets of points in $P$ proposed in [48]. The intrinsic spread is invariant by affine transformation, but is still not an invariant of the problem.

[^15]:    ${ }^{6}$ This definition is inspired by the definition of depth in [17, 72] where the depth of the segment $p_{a} p_{b}$ is the minimum number of points of $P \backslash\left\{p_{a}, p_{b}\right\}$ on either side of the line $p_{a} p_{b}$.

[^16]:    ${ }^{7}$ The upper bound proved in [17] is $2 n-2$.

[^17]:    ${ }^{1}$ This definition resembles but is not exactly the same as the depth used in [17]. It is also similar to the crossing depth defined in Chapter 3.

[^18]:    ${ }^{1}$ This definition resembles but is not the same as the depth used in [17].

[^19]:    ${ }^{1}$ This was discussed at the workshop [86].

[^20]:    ${ }^{2}$ This was also discussed at the workshop [86].

[^21]:    ${ }^{3}$ A fence only has quadrilateral situations and all of them are dead-ends. Each segment of a fence (except the leftmost and rightmost ones) participates in two quadrilateral situations. The author currently believes that this property optimizes the number of crossings while having only dead-end situations, and that is is achieved only by a fence, hinting that the lower bound provided by Theorem 5.1.1 may be tight.

[^22]:    ${ }^{4}$ The author thinks that knowledge, and maybe even truth, is more a collection of open questions than a series of answers.
